Sex therapists have expanded on and modified these procedures over the years to take advantage of recent advances in knowledge (see, for example, Bancroft, 1997; Rosen, 2007; Wincze, 2009; Wincze et al., 2008). Results with sex therapy for erectile dysfunction indicate that as many as 60% to 70% of the cases show a positive treatment outcome for at least several years, although there may be some slipping after that (Rosen, 2007; Sarwer & Durlak, 1997; Segraves & Althof, 1998). For better treatment of specific sexual dysfunctions, sex therapists integrate specific procedures into the context of general sex therapy. For example, to treat premature ejaculation, most sex therapists use a procedure developed by Semans (1956), sometimes called the *squeeze* technique, in which the penis is stimulated, usually by the partner, to nearly full erection. At this point, the partner firmly squeezes the penis near the top where the head of the penis joins the shaft, which quickly reduces arousal. These steps are repeated until (for heterosexual partners) eventually the penis is briefly inserted in the vagina without thrusting. If arousal occurs too quickly, the penis is withdrawn and the squeeze technique is employed again. In this way, the man develops a sense of control over arousal and ejaculation. Reports of success with this approach over the past 20 years suggest that 60% to 90% of men benefit, but the success rates drop to about 25% after 3 years or more of follow-up (Althof, 2007; Polonsky, 2000). Gary, the 31-year-old salesman, was treated with this method, and his wife was cooperative during the procedures. Brief marital therapy also persuaded Gary that his insecurity over his perception that his wife no longer found him attractive was unfounded. After treatment, he reduced his work hours somewhat, and the couple's marital and sexual relations improved.

Lifelong female orgasmic disorder may be treated with explicit training in masturbatory procedures. For example, Greta was still unable to achieve orgasm with manual stimulation by her husband, even after proceeding through the basic steps of sex therapy. At this point, following certain standardized treatment programs for this problem (see, for example, Heiman, 2000; Heiman & LoPiccolo, 1988), Greta and Will purchased a vibrator and Greta was taught to let go of her inhibitions by talking out loud about how she felt during sexual arousal, even shouting or screaming if she wanted to. In the context of appropriate genital pleasuring and disinhibition exercises, the vibrator brought on Greta's first orgasm. With practice and good communication, the couple eventually learned how to bring on Greta's orgasm without the vibrator. Although Will and Greta were both delighted with her progress, Will was concerned that Greta's screams during orgasm would attract the attention of the neighbors. When they planned a vacation at a lake, they were concerned about whether the cabin had electricity to power the vibrator in case they needed it. Summaries of results from a number of studies suggest 70% to 90% of women will benefit from treatment, and these gains are stable and even improve further over time (Heiman, 2007; Heiman & Meston, 1997; Segraves & Althof, 1998).

To treat vaginismus, the woman and, eventually, the partner gradually insert increasingly larger dilators at the woman's pace. After the woman (and then the partner) can insert the largest dilator, in a heterosexual couple, the woman gradually inserts the

▲ A therapist usually treats a dysfunction in one partner by seeing the couple together.

man's penis. These exercises are carried out in the context of genital and nongenital pleasuring so as to retain arousal. Close attention must be accorded to any increased fear and anxiety that may be associated with the process, which may trigger memories of early sexual abuse that may have contributed to the onset of the condition. These procedures are highly successful, with a large majority of women (80% to 100%) overcoming vaginismus in a relatively short period (Beck, 1993; Binik et al., 2007; Leiblum & Rosen, 2000; Segraves & Althof, 1998; ter Kuile et al., 2007).

A variety of treatment procedures have also been developed for low sexual desire (see, for example, Pridal & LoPiccolo, 2000; Wincze, 2009; Wincze & Carey, 2001). At the heart of these treatments are the standard reeducation and communication phases of traditional sex therapy with, possibly, the addition of masturbatory training and exposure to erotic material. Each case may require individual strategies. Remember Mrs. C., who was sexually abused by her cousin? Therapy involved helping the couple understand the impact of the repeated, unwanted sexual experiences in Mrs. C.'s past and to approach sex so that Mrs. C. was more comfortable with foreplay. She gradually lost the idea that once sex was started she had no control. She and her husband worked on starting and stopping sexual encounters. Cognitive restructuring was used to help Mrs. C. interpret her husband's amorousness in a positive rather than a skeptical light. In general, approximately 50% to 70% of individuals with low sexual desire benefit from sex therapy, at least initially (Basson, 2007; Brotto, 2006; Hawton, 1995; Segraves & Althof, 1998).

### Medical Treatments

A variety of pharmacological and surgical techniques have been developed in recent years to treat sexual dysfunction, almost all focusing on male erectile disorder. The drug Viagra, introduced in 1998, and similar drugs such as Levitra and Cialis, introduced subsequently, are the best known. We look at the four most popular procedures: oral medication, injection of vasoactive substances directly into the penis, surgery, and vacuum device therapy. Before we begin, note that it is important to combine any medical treatment with a comprehensive educational and sex therapy program to ensure maximum benefit.

In 1998, the drug sildenafil (trade name Viagra) was introduced for erectile dysfunction. Approval from the Food and Drug Administration occurred early in 1998, and results from several clinical trials suggested that between 50% and 80% of a large number of men benefit from this treatment (Conti, Pepine, & Sweeney, 1999; Goldstein et al., 1998) in that erections become sufficient for intercourse, compared to approximately 30% who benefit from placebo. Results are similar with Cialis and Levitra (Carrier et al., 2005). However, as many as 30% of men may suffer severe headaches as a side effect, particularly at higher doses (Rosen, 2000, 2007; Virag, 1999), and reports of sexual satisfaction are not optimal. For example, Virag (1999) evaluated a large number of men treated with Viagra and found that 32% of the men were successful if success was defined as an erection sufficient to engage in intercourse and satisfaction of at least 7 on the 0-to-10 scale. Results were categorized as fair for 29% who reported adequate erection but satisfaction from 4 to 6, and unsatisfactory for 39% with inadequate erection and satisfaction rated as 0 to 3. Thus, erections were sufficiently firm for intercourse in 61% of the men, consistent with other studies, but only 32% rated the results as at least good, suggesting the need for, perhaps, additional drug or psychological treatment. If men are particularly anxious about sex, results are not as good with the drug (Rosen et al., 2006). Also, the large majority of men stop using the drug after a trial of several months or a year, indicating less than satisfactory long-term results (Rosen, 2007). To address this issue Bach, Barlow, and Wincze (2004) evaluated the addition of cognitive-behavioral treatment (CBT) to treatment with Viagra. Results were encouraging because couples reported greater satisfaction and increased sexual activity after combined drug therapy and CBT, compared to a period when only the drug was used.

There was also some hope that Viagra would be useful for dysfunction in postmenopausal women, but results were disappointing (Kaplan et al., 1999). Berman and colleagues (2003) reported some improvement from Viagra in postmenopausal women with female sexual arousal disorder, but only in those women without diminished sexual desire.

For some time, testosterone (Schiavi, White, Mandeli, & Levine, 1997) has been used to treat erectile dysfunction. But although it is safe and has relatively few side effects, only negligible effects on erectile dysfunction have been reported (Mann et al., 1996). Some urologists teach patients to inject vasodilating drugs such as *papaverine* or *prostaglandin* directly into the penis when they want to have sexual intercourse. These drugs dilate the blood vessels, allowing blood to flow to the penis and thereby producing an erection within 15 minutes that can last from 1 to 4 hours (Kim & Lipshultz, 1997; Rosen, 2007; Segraves & Althof, 1998). Because this procedure is a bit painful (although not as much as you might think), a substantial number of men, usually 50% to 60%, stop using it after a short time. In one study, 50 of 100 patients discontinued papaverine for various reasons (Lakin, Montague, Vanderbrug Medendorp, Tesar, & Schover, 1990; Segraves & Althof, 1998). A soft capsule that contains papaverine (called MUSE [Medical Urethral System for Erections]) can be inserted directly into the urethra, but this is somewhat painful, is less effective than injections, and remains awkward and artificial enough to preclude wide acceptance (Delizonna, Wincze, Litz, Brown, & Barlow, 2001). On the other hand, Heiman and colleagues (2006) recently demonstrated that topical application of papaverine externally to women's genitalia produced vasocongestion and arousal in postmenopausal woman compared to placebo in the laboratory. Studies must now determine whether this drug treatment is effective outside of the laboratory.

Insertion of *penile prostheses* or implants has been a surgical option for almost 100 years; only recently are they good enough to approximate normal sexual functioning. One procedure involves implanting a semirigid silicone rod that can be bent by the male into correct position for intercourse and maneuvered out of the way at other times. In a more popular procedure, the male squeezes a small pump that is surgically implanted into the scrotum, forcing fluid into an inflatable cylinder and thus producing an erection. A newer penile prosthetic device is an inflat-

©Larry Mulvehill/The Image Works

▲ An inflatable penile implant may be used for men with inadequate sexual functioning.

able rod that contains the pumping device, which is more convenient than having the pump outside the rod. However, surgical implants fall short of restoring presurgical sexual functioning or assuring satisfaction in most patients (Gregoire, 1992; Kim & Lipshultz, 1997); they are now generally used only if other approaches don't work. On the other hand, this procedure has proved useful for men who must have a cancerous prostate removed, because this surgery often causes erectile dysfunction, although newer "nerve-sparing" surgeries lessen the effect to some extent (Ramsawh, Morgentaler, Covino, Barlow, & DeWolf, 2005).

Another approach is *vacuum device therapy,* which works by creating a vacuum in a cylinder placed over the penis. The vacuum draws blood into the penis, which is then trapped by a specially designed ring placed around the base of the penis. Although using the vacuum device is rather awkward, between 70% and 100% of users report satisfactory erections, particularly if psychological sex therapy is ineffective (Segraves & Althof, 1998; Witherington, 1988). The procedure is also less intrusive than surgery or injections, but it remains awkward and artificial (Delizonna et al., 2001).

### Summary

Treatment programs, both psychosocial and medical, offer hope to most people who suffer from sexual dysfunctions. Unfortunately, such programs are not readily available in many locations because few health and mental health professionals are trained to apply them, although the availability of drugs for male erectile dysfunction is widespread. Psychological treatment of sexual arousal disorders requires further improvement, and treatments for low sexual desire are largely untested. New medical developments appear yearly, but most are still intrusive and clumsy, although drugs such as Viagra and Levitra exhibit some success for erectile dysfunction and many more such drugs are in development.

Unfortunately, most health professionals tend to ignore the issue of sexuality in older adults. Along with the usual emphasis on communication, education, and sensate focus, appropriate lubricants for women and a discussion of methods to maximize the erectile response in men should be a part of any sexual counseling for older couples. More important, even with reduced physical capabilities, continued sexual relations, not necessarily including intercourse, should be an enjoyable and important part of an aging couple's relationship. Further research and development in the treatment of sexual dysfunction must address all these issues. Nevertheless, the overwhelming consensus is that a combination of psychological and drug treatment, when indicated, will continue to be the treatment strategy of choice.

### Concept Check 10.3

Determine whether the following statements are true (T) or false (F) in regard to the causes and treatments of sexual dysfunctions.

1. _____ Many physical and medical conditions and their treatments (for example, prescription medications) contribute to sexual dysfunction; however, many doctors are unaware of the connection.
2. _____ Anxiety always decreases or even eradicates sexual arousal.
3. _____ Sexual dysfunctions can result from a growing dislike for a partner, traumatic sexual events, or childhood lessons about the negative consequences of sexual behavior.
4. _____ A simple, effective treatment for many disorders is education.
5. _____ All sexual dysfunctions are treated with the same psychosocial technique.
6. _____ Most surgical and pharmacological treatments of recent years have focused on male erectile disorder.

## Paraphilia: Clinical Descriptions

If you are like most people, your sexual interest is directed to other physically mature adults (or late adolescents), all of whom are capable of freely offering or withholding their consent. But what if you are sexually attracted to something or somebody other than another adult, such as animals (particularly horses and dogs) (Williams & Weinberg, 2003) or a vacuum cleaner? (Yes, it does happen!) Or what if your only means of obtaining sexual satisfaction is to commit a brutal murder? Such patterns of sexual arousal and countless others exist in a large number of individuals, causing untold human suffering both for them and, if their behavior involves other people, for their victims. As noted in the beginning of the chapter, these disorders of sexual arousal are called **paraphilias**.

Over the years, we have assessed and treated a large number of these individuals, ranging from the slightly eccentric and sometimes pitiful case to some of the most dangerous killer–rapists encountered anywhere. But it is also the case that there are many harmless aberrations, such as some fetishistic arousal patterns (see next section), that harm no one, are not distressful or impairing, and therefore do not meet criteria for a disorder. We begin by describing briefly the major types of paraphilia, using in all instances cases from our own files. As with sexual dysfunctions, it is unusual for an individual to have just one paraphilic pattern of sexual arousal (Bradford & Meston, in press; Laws & O'Donohue, 2008). Many of our patients may present with two, three, or more patterns, although one is usually dominant (Abel et al., 1987; Abel, Becker, Cunningham-Rathner, Mittelman, & Rouleau, 1988; Brownell, Hayes, & Barlow, 1977). Furthermore,

▲ A crowded subway car is a typical setting for frotteuristic activity, in which a person takes advantage of forced physical contact with strangers to become aroused.

©Robert Brenner/PhotoEdit

it is not uncommon for individuals with paraphilia to also suffer from comorbid mood, anxiety, and substance abuse disorders (Kafka & Hennen, 2003; Raymond, Coleman, Ohlerking, Christenson, & Miner, 1999). Although paraphilias are not widely prevalent and estimates of their frequency are hard to come by, some disorders, such as transvestic fetishism (cross-dressing, discussed later), seem relatively common (Bancroft, 1989; Mason, 1997). You may have been the victim of **frotteurism** in a large city, typically on a crowded subway or bus. (We mean really crowded, with people packed in like sardines.) In this situation, women have been known to experience more than the usual jostling and pushing from behind. What they discover, much to their horror, is a male with a frotteuristic arousal pattern rubbing against them until he is stimulated to the point of ejaculation. Because the victims cannot escape easily, the frotteuristic act is usually successful (Lussier & Piché, 2008).

## Fetishism

In **fetishism**, a person is sexually attracted to nonliving objects. There are almost as many types of fetishes as there are objects, although women's undergarments and shoes are popular (Darcangelo, 2008). Fetishistic arousal is associated with two classes of objects or activities: (1) an inanimate object or (2) a source of specific tactile stimulation, such as rubber, particularly clothing made out of rubber. Shiny black plastic is also used (Bancroft, 1989; Junginger, 1997). Most of the person's sexual fantasies, urges, and desires focus on this object. A third source of attraction (sometimes called *partialism*) is a part of the body, such as the foot, buttocks, or hair, but this attraction is no longer technically classified as a fetish because distinguishing it from more normal patterns of arousal is often difficult.

In one U.S. city for several months, bras hung out on a woman's backyard clothesline disappeared. The women in the neighborhood soon began talking to each other and discovered that bras were missing from every clothesline for blocks around. A police stakeout caught the perpetrator, who turned out to have a strong fetish for brassieres. As another example of fetishistic behavior related to tactile stimulation, it is relatively common for a urologist to be called to the emergency room to remove surgically a long thin object, such as a pencil or the arm of an eyeglass frame, from a man's urethra. Men who insert such objects think that partially blocking the urethra in this way can increase the intensity of ejaculation during masturbation. However, if the entire object slips into the penis, major medical intervention is required.

**DSM-IV-TR** **Table 10.8** Criteria for Frotteurism

**A.** Over a period of at least 6 months, recurrent, intense sexually arousing fantasies, sexual urges, or behaviors involving touching and rubbing against a nonconsenting person.

**B.** The person has acted on these sexual urges, or the sexual urges or fantasies cause marked distress or interpersonal difficulty.

## Voyeurism and Exhibitionism

**Voyeurism** is the practice of observing, to become aroused, an unsuspecting individual undressing or naked. **Exhibitionism**, by contrast, is achieving sexual arousal and gratification by exposing genitals to unsuspecting strangers. Consider the case of Robert.

### ROBERT | *Outside the Curtains*

Robert, a 31-year-old, married, blue-collar worker, reported that he first started "peeping" into windows when he was 14. He rode around the neighborhood on his bike at night,

**DSM-IV-TR** **Table 10.9** Criteria for Fetishism

**A.** Over a period of at least 6 months, recurrent, intense sexually arousing fantasies, sexual urges, or behaviors involving the use of nonliving objects (e.g., female undergarments).

**B.** The fantasies, sexual urges, or behaviors cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

**C.** The fetish objects are not limited to articles of female clothing used in cross-dressing (as in transvestic fetishism) or devices designed for the purpose of tactile genital stimulation (e.g., a vibrator).

*Source:* Reprinted, with permission, from American Psychiatric Association. (2000). *Diagnostic and statistical manual of mental disorders* (4th ed., text revision). Washington, DC: Author, © 2000 American Psychiatric Association.

and when he spotted a female through a window he stopped and stared. During one of these episodes, he felt the first pangs of sexual arousal. Eventually he began masturbating while watching, thereby exposing his genitals, although out of sight. When he was older, he drove around until he spotted some prepubescent girls. He parked his car near them, unzipped his fly, called them over, and attempted to carry on a nonsexual conversation. Later he was sometimes able to talk a girl into mutual masturbation and *fellatio,* or oral stimulation of the penis. Although he was arrested several times, paradoxically, the threat of arrest increased his arousal (Barlow & Wincze, 1980).

Remember that anxiety actually increases arousal under some circumstances. Many voyeurs just don't get the same satisfaction from attending readily available strip shows at a local bar. Exhibitionism is often associated with lower levels of education, but not always. Note again that the thrilling element of risk is an important part of exhibitionism.

### The Lawyer Who Needed the Bus

Several years ago, a distinguished lawyer reported that he needed help and that his career was on the line. An intelligent, good-looking single man, he noted without bragging that he could have sex with any number of beautiful women in the course of his law practice. However, the only way he could become aroused was to leave his office, go down to the bus stop, ride around the city until a reasonably attractive young woman got on, expose himself just before the next stop, and then run off the bus, often with people chasing after him. To achieve maximal arousal, the bus could not be full or empty; there had to be just a few people sitting on the bus, and the woman getting on had to be the right age. Sometimes hours would pass before these circumstances lined up correctly. The lawyer observed that if he was not fired for exhibitionism he would be fired for all the time he was missing from work. On several occasions he had requested a girlfriend to role-play sitting on a bus in his apartment. Although he exposed himself to her, he could not achieve sexual arousal and gratification because the activity just wasn't exciting.

Although prevalence is unknown (Murphy & Page, 2008), in a random sample of 2,450 adults in Sweden, 31% reported at least one incident of being sexually aroused by exposing their genitals to a stranger and 7.7% reported at least one incident of being sexually aroused by spying on others having sex (Langstrom & Seto, 2006). To meet diagnosis for exhibitionism, the behavior must occur repeatedly and be compulsive or out of control.

## Transvestic Fetishism

In **transvestic fetishism**, sexual arousal is strongly associated with the act of dressing in clothes of the opposite sex, or cross-dressing (Wheeler, Newring, & Draper, 2008). Consider the case of Mr. M.

**DSM-IV-TR** **Table 10.10** Criteria for Voyeurism and Exhibitionism

Voyeurism

**A.** Over a period of at least 6 months, recurrent, intense sexually arousing fantasies, sexual urges, or behaviors involving the act of observing an unsuspecting person who is naked, in the process of disrobing, or engaging in sexual activity.

**B.** The person has acted on these sexual urges, or the sexual urges or fantasies cause marked distress or interpersonal difficulty.

Exhibitionism

**A.** Over a period of at least 6 months, recurrent, intense sexually arousing fantasies, sexual urges, or behaviors involving the exposure of one's genitals to an unsuspecting stranger.

**B.** The person has acted on these sexual urges, or the sexual urges or fantasies cause marked distress or interpersonal difficulty.

### MR. M. | *Strong Man in a Dress*

Mr. M., a 31-year-old married police officer, came to our clinic seeking treatment for uncontrollable urges to dress in women's clothing and appear in public. He had been doing this for 16 years and had been discharged from the Marine Corps for cross-dressing. Since then, he had risked public disclosure on several occasions. Mr. M.'s wife had threatened to divorce him because of the cross-dressing, yet she often purchased women's clothing for him and was "compassionate" while he wore them.

Note that Mr. M. was in the Marine Corps before he joined the police force. It is not unusual for males who are strongly inclined to dress in female clothes to compensate by associating with so-called macho organizations. Some of our cross-dressing patients have been associated with various paramilitary organizations. Nevertheless, most individuals with this disorder do not seem to display any compensatory behaviors. The same survey in Sweden

**DSM-IV-TR** **Table 10.11** Criteria for Transvestic Fetishism

**A.** Over a period of at least 6 months, in a heterosexual male, recurrent, intense sexually arousing fantasies, sexual urges, or behaviors involving cross-dressing.

**B.** The fantasies, sexual urges, or behaviors cause clinically significant distress or impairment in social, occupational, or other important areas of functioning. Specify if:

With gender dysphoria: If the person has persistent discomfort with gender role or identity

*Source:* Reprinted, with permission, from American Psychiatric Association. (2000). *Diagnostic and statistical manual of mental disorders* (4th ed., text revision). Washington, DC: Author, © 2000 American Psychiatric Association.

mentioned earlier found 2.8% of men and 0.4% of women reported at least one episode of transvestic fetishism (Langstrom & Zucker, 2005).

Interestingly, the wives of many men who cross-dress have accepted their husbands' behavior and can be quite supportive if it is a private matter between them. Docter and Prince (1997) reported that 60% of more than 1,000 men with transvestic fetishism were married at the time of the survey. Some people, both married and single, join cross-dressing clubs that meet periodically or subscribe to newsletters devoted to the topic. Research suggests that transvestic fetishism is indistinguishable from other fetishes in most respects (Freund, Seto, & Kuban, 1996).

## Sexual Sadism and Sexual Masochism

Both **sexual sadism** and **sexual masochism** are associated with either inflicting pain or humiliation (sadism) or suffering pain or humiliation (masochism) (Hucker, 2008; Yates, Hucker, & Kingston, 2008). Although Mr. M. was extremely concerned about his cross-dressing, he was also disturbed by another problem. To maximize his sexual pleasure during intercourse with his wife, he had her wear a collar and leash, tied her to the bed, and handcuffed her. He sometimes tied himself with ropes, chains, handcuffs, and wires, all while he was cross-dressed. Mr. M. was concerned he might injure himself seriously. As a member of the police force, he had heard of cases and even investigated one himself in which an individual was found dead, tightly and completely bound in harnesses, handcuffs, and ropes. In many such cases, something goes wrong and the individual accidentally hangs himself, an event that should be distinguished from the closely related condition called *hypoxiphilia,* which involves self-strangulation to reduce the flow of oxygen to the brain and enhance the sensation of orgasm. It may seem paradoxical that someone has to either inflict or receive pain to become sexually aroused, but these types of cases are not uncommon. On many occasions, the behaviors themselves are quite mild and harmless (Krueger, 2010), but they can become dangerous and costly. It was not unusual that Mr. M. presented with three patterns of deviant arousal—in his case, sexual masochism, sexual sadism, and transvestic fetishism.

**DSM-IV-TR** **Table 10.12** Criteria for Sexual Sadism and Sexual Masochism

Sexual Sadism

**A.** Over a period of at least 6 months, recurrent, intense sexually arousing fantasies, sexual urges, or behaviors involving acts (real, not simulated) in which the psychological or physical suffering (including humiliation) of the victim is sexually exciting to the person.

**B.** The person has acted on these sexual urges with a nonconsenting person, or the sexual urges or fantasies cause marked distress or interpersonal difficulty.

Sexual Masochism

**A.** Over a period of at least 6 months, recurrent, intense sexually arousing fantasies, sexual urges, or behaviors involving the act (real, not simulated) of being humiliated, beaten, bound, or otherwise made to suffer.

**B.** The fantasies, sexual urges, or behaviors cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

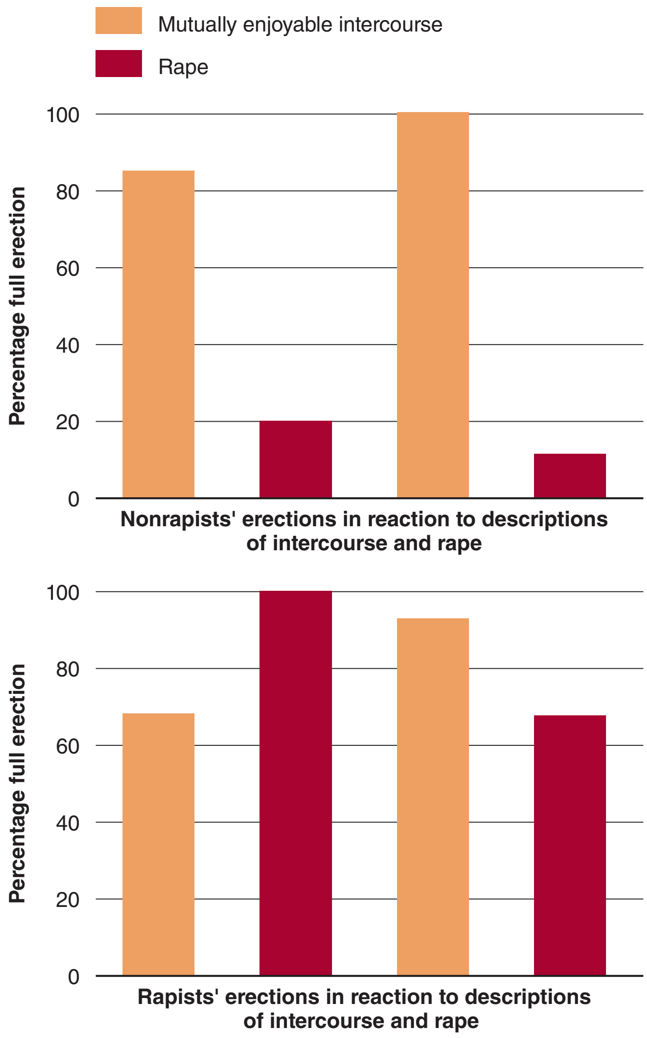
▲ Murderer Jeffrey Dahmer obtained sexual gratification from acts of sadism and cannibalism. (In prison, he was killed by fellow inmates.)

### *Sadistic Rape*

After murder, rape is the most devastating assault one person can make on another. It is not classified as a paraphilia because most instances of rape are better characterized as an assault by a male (or, quite rarely, a female) whose patterns of sexual arousal are not paraphilic. Instead, many rapists meet criteria for antisocial personality disorder (see Chapter 12) and may engage in a variety of antisocial and aggressive acts (Bradford & Meston, in press; McCabe & Wauchope, 2005; Quinsey, 2010). Many rapes could be described as opportunistic, in that an aggressive or antisocial individual with a marked lack of empathy and disregard for inflicting pain on others (Bernat, Calhoun, & Adams, 1999) spontaneously took advantage of a vulnerable and unsuspecting woman. These unplanned assaults often occur during robberies or other criminal events. Rapes can also be motivated by anger and vindictiveness against specific women and may have been planned in advance (Hucker, 1997; Knight and Prentky, 1990; McCabe & Wauchope, 2005; Quinsey, 2010).

A number of years ago, we determined in our sexuality clinic that certain rapists do fit definitions of paraphilia closely and could probably better be described as sadists, a finding that has since been confirmed (McCabe & Wauchope, 2005; Qinsey, 2010). We constructed two audiotapes on which were described (1) mutually enjoyable sexual intercourse and (2) sexual intercourse involving force on the part of the male (rape). Each tape was played twice for selected listeners. Response differences between rapists and nonrapists are presented in ■ Figure 10.6 (Abel, Barlow, Blanchard, & Guild, 1977). As you can see, the nonrapists became sexually aroused to descriptions of mutually consenting intercourse but not to those involving force. Rapists, however, became aroused by both types of descriptions.

Among the rapists we were evaluating, a subgroup seemed to be particularly aroused when force and acts of cruelty were involved. To assess this reaction more completely, we put together a third audiotape consisting of aggression and assault without any sexual content. A number of individuals displayed strong sexual arousal to nonsexual aggressive themes, as well as to rape, and little or no arousal to mutually enjoyable intercourse, as depicted by the data from one individual in ■ Figure 10.7. This man was the most brutal rapist we have ever encountered. By his own report, he had raped more than 100 times. His last victim spent 2 weeks in the hospital recover-



■ **FIGURE 10.6** Erectile arousal differences between rapists and nonrapists. Nonrapists became aroused to descriptions of mutually enjoyable intercourse but not to descriptions of rape; rapists experienced significant arousal to both types of descriptions. (Reprinted, with permission, from Abel, G. G., Barlow, D. H., Blanchard, E. B., & Guild, D. (1977). The components of rapists' sexual arousal. *Archives of General Psychiatry, 34,* 895–903, © 1977 American Medical Association.)

ing from various injuries. He would bite his victim's breasts, burn her with cigarettes, beat her with belts and switches, and pull out her pubic hair while shoving objects in her vagina. Although some evidence indicated he had killed at least three of his victims, it was not sufficient to convict him. Nevertheless, he was convicted of multiple assaults and rapes and was about to begin a life sentence in a closely guarded area of the maximum-security state prison. Realizing his behavior was hopelessly out of control, he was eager to get there. He reported that all his waking hours were spent ruminating uncontrollably on sadistic fantasies. He knew he was going to spend the rest of his life in prison, probably in solitary confinement, but hoped there was something we could do to relieve him of his obsession. By any definition, this man met criteria for sexual sadism.

## Pedophilia and Incest

©Reuters/Corbis

▲ In 2002, the Catholic Church in the United States was forced to acknowledge a series of cover-ups involving pedophilia by a number of clergy that went back several decades.

Perhaps the most tragic sexual deviance is a sexual attraction to children (or young adolescents), called **pedophilia** (Blanchard, 2010; Seto, 2009). People around the world have become more aware of this problem following the well-publicized scandal in the Catholic Church, where priests, many of whom undoubtedly met criteria for pedophilia, abused children repeatedly, only to be transferred to another church where they would do it again. Individuals with this pattern of arousal may be attracted to male children, female children, or both. In one survey, as many as 12% of men and 17% of women reported being touched inappropriately by adults when they were children; another survey estimated that the number of sexually abused children rose 125% in the 1990s to more than 330,000 children in the United States (Fagan, Wise, Schmidt, & Berlin, 2002). Approximately 90% of abusers are male, and 10% are female (Fagan et al., 2002; Seto, 2009). Much as with adult rape, as many as 40% to 50% of sexual offenders do not have pedophilic arousal patterns and do not meet criteria for pedophilia. Rather, their offences are associated with brutal antisocial and aggressive opportunistic acts (Blanchard, 2010; Seto, 2009). Child pornography investigations have made much news lately, and individuals convicted of downloading child pornography often defend themselves by pointing out that they were "just looking" and are not pedo-

### DSM-IV-TR **Table 10.13** Criteria for Pedophilia

**A.** Over a period of at least 6 months, recurrent, intense sexually arousing fantasies, sexual urges, or behaviors involving sexual activity with a prepubescent child or children (generally age 13 years or younger).

**B.** The person has acted on these sexual urges, or the sexual urges or fantasies cause marked distress or interpersonal difficulty.

**C.** The person is at least age 16 years and at least 5 years older than the child or children in criterion A.

Note: Do not include an individual in late adolescence involved in an ongoing sexual relationship with a 12- or 13-year-old.

Specify if:
- Sexually attracted to males
- Sexually attracted to females
- Sexually attracted to both

Specify if:
- Limited to incest

Specify type:
- Exclusive type (attracted only to children)
- Nonexclusive type

**■ FIGURE 10.7** One sadist's erections on listening to audiotape of nonsexual aggression, rape, and intercourse descriptions. (Reprinted, with permission, from Abel, G. G., Barlow, D. H., Blanchard, E. B., & Guild, D. (1977). The components of rapists' sexual arousal. *Archives of General Psychiatry, 34,* 895–903, © 1977 American Medical Association.)

philes. But now an important study indicates that being charged with a child pornography offense is one of the best diagnostic indications of pedophilia (Seto, Cantor, & Blanchard, 2006).

If the children are the person's relatives, the pedophilia takes the form of **incest**. Although pedophilia and incest have much in common, victims of pedophilia tend to be young children and victims of incest tend to be girls beginning to mature physically (Rice & Harris, 2002). Marshall, Barbaree, and Christophe (1986) and Marshall (1997) demonstrated by using penile strain gauge measures that incestuous males are, in general, more aroused by adult women than are males with pedophilia, who tend to focus exclusively on children. Thus, incestuous relations may have more to do with availability and interpersonal issues ongoing in the family than pedophilia, as in the case of Tony.

### TONY | *More and Less a Father*

Tony, a 52-year-old married television repairman, came in depressed. About 10 years earlier he had begun sexual activity with his 12-year-old daughter. Light kissing and some fondling gradually escalated to heavy petting and, finally, mutual masturbation. When his daughter was 16 years old, his wife discovered the ongoing incestuous relationship. She separated from her husband and eventually divorced him, taking her daughter with her. Soon, Tony remarried. Just before his initial visit to our clinic, Tony visited his daughter, then 22 years old, who was living alone in a different city. They had not seen each other for 5 years. A second visit, shortly after the first, led to a recurrence of the incestuous behavior. At this point, Tony became extremely depressed and told his new wife the whole story. She contacted our clinic with his full cooperation while his daughter sought treatment in her own city.

We return to the case of Tony later, but several features are worth noting. First, Tony loved his daughter and was bitterly disappointed and depressed over his behavior. Occasionally, a child molester is abusive and aggressive, sometimes killing the victims; in these cases, the disorder is often both sexual sadism and pedophilia. But most child molesters are *not* physically abusive. Rarely is a child physically forced or injured. From the molester's perspective, no harm is done because there is no physical force or threats. Child molesters often rationalize their behavior as "loving" the child or teaching the child useful lessons about sexuality. The child molester almost never considers the psychological damage the victim suffers, yet these interactions often destroy the child's trust and ability to share intimacy. Child molesters rarely gauge their power over the children, who may participate in the molestation without protest yet be frightened and unwilling. Often children feel responsible for the abuse because no outward force or threat was used by the adult, and only after the abused children grow up are they able to understand they were powerless to protect themselves and not responsible for what was done to them.

**DSM-IV-TR** **Table 10.14** Criteria for Paraphilia Not Otherwise Specified

This category is included for coding paraphilias that do not meet the criteria for any of the specific categories. Examples include, but are not limited to, telephone scatologia (obscene phone calls), necrophilia (corpses), partialism (exclusive focus on part of body), zoophilia (animals), coprophilia (feces), klismaphilia (enemas), and urophilia (urine).

## Paraphilia in Women

Paraphilia is seldom seen in women and was thought to be absent in women for many years, with the possible exception of sadomasochistic practices. But in recent years, several reports have appeared describing individual cases or small series of cases (Seto, 2009). Now estimates suggest that approximately 5% to 10% of all sexual offenders are women (Logan, 2009; Wiegel, 2008). For example, Federoff, Fishell, and Federoff (1999) have reported 12 cases of women with paraphilia seen in their clinic. Although some women had more than one paraphilia, 5 of the 12 presented with pedophilia, 4 presented with exhibitionism, and 3 presented with sadomasochistic tendencies.

To take several examples, one heterosexual woman was convicted of sexually molesting an unrelated 9-year-old boy while she was babysitting. It seems she had touched the boy's penis and asked him to masturbate in front of her while she watched religious programs on television. It is not unusual for individuals with paraphilia to rationalize their behavior by engaging in some other practices that they consider to be morally correct or uplifting at the same time. Yet another woman came to treatment because of her "uncontrollable" rituals of undressing in front of her apartment window and masturbating approximately five times a month. In addition she would, occasionally, drive her truck through the neighborhood, where she would attempt to befriend cats and dogs by offering them food. She would then place honey or other food substances on her genital area so that the animals would lick her. As with most people with paraphilias, the woman was horrified by this activity and was seeking treatment to eliminate it, although she found it highly sexually arousing. Wiegel (2008) reported on more than 175 females who admitted sexually abusing children or adolescents.

## Causes of Paraphilia

Although no substitute for scientific inquiry, case histories often provide hypotheses that can then be tested by controlled scientific observations. Let's return to the cases of Robert and Tony to see if their histories contain any clues.

### **ROBERT** | *Revenge on Repression*

Robert (who sought help for exhibitionism) was raised by a stern authoritarian father and a passive mother in a small Texas town. His father, who was a firm believer in old-time religion, often preached the evils of sexual intercourse to his family. Robert learned little about sex from his father except that it was bad, so he suppressed any emerging heterosexual urges and fantasies and as an adolescent felt uneasy around girls his own age. By accident, he discovered a private source of sexual gratification: staring at attractive and unsuspecting females through the window. This led to his first masturbatory experience.

Robert reported in retrospect that being arrested was not so bad because it disgraced his father, which was his only way of getting back at him. The courts treated him lightly (which is not unusual), and his father was publicly humiliated, forcing the family to move from their small Texas town (Barlow & Wincze, 1980).

### **TONY** | *Trained Too Young*

Tony, who sought help because of an incestuous relationship with his daughter, reported an early sexual history that contained a number of interesting events. Although he was brought up in a reasonably loving and outwardly normal Catholic family, he had an uncle who did not fit the family pattern. When he was 9 or 10, Tony was encouraged by his uncle to observe a game of strip poker that the uncle was playing with a neighbor's wife. During this period, he also observed his uncle fondling a waitress at a drive-in restaurant and shortly thereafter was instructed by his uncle to fondle his young female cousin. Thus, he had an early model for mutual fondling and masturbation and obtained some pleasure from interacting in this way with young girls. Although the uncle never touched Tony, his behavior was clearly abusive. When Tony was about 13, he engaged in mutual manipulation with a sister and her girlfriend, which he remembers as pleasurable. Later, when Tony was 18, a brother-in-law took him to a prostitute and he first experienced sexual intercourse. He remembered this visit as unsatisfactory because, on that and subsequent visits to prostitutes, he ejaculated prematurely—a sharp contrast to his early experience with young girls. Other experiences with adult women were also unsatisfactory. When he joined the service and was sent overseas, he sought out prostitutes who were often as young as 12.

These cases remind us that deviant patterns of sexual arousal often occur in the context of other sexual and social problems. Undesired kinds of arousal may be associated with deficiencies in levels of "desired" arousal with consensual adults; this was certainly true for both Tony and Robert, whose sexual relationships with adults were incomplete. In many cases, an inability to develop adequate social relations with the appropriate people for sexual relationships seems to be associated with a developing of inappropriate sexual outlets (Barlow & Wincze, 1980; Marshall, 1997). Indeed, integrated theories of the causes of paraphilias all note the presence of disordered relationships during childhood and adolescence with resulting deficits in healthy sexual development (Marshall & Barbaree, 1990; Ward & Beech, 2008). However, many people with deficient sexual and social skills do not develop deviant patterns of arousal.

Early experience seems to have an effect that may be quite accidental. Tony's early sexual experiences just happened to be of the type he later found sexually arousing. Many pedophiles also report being abused themselves as children, which turns out to be a strong predictor of later sexual abuse by the victim (Fagan et al., 2002). Robert's first erotic experience occurred while he was "peeping." But many of us do not find our early experiences reflected in our sexual patterns.

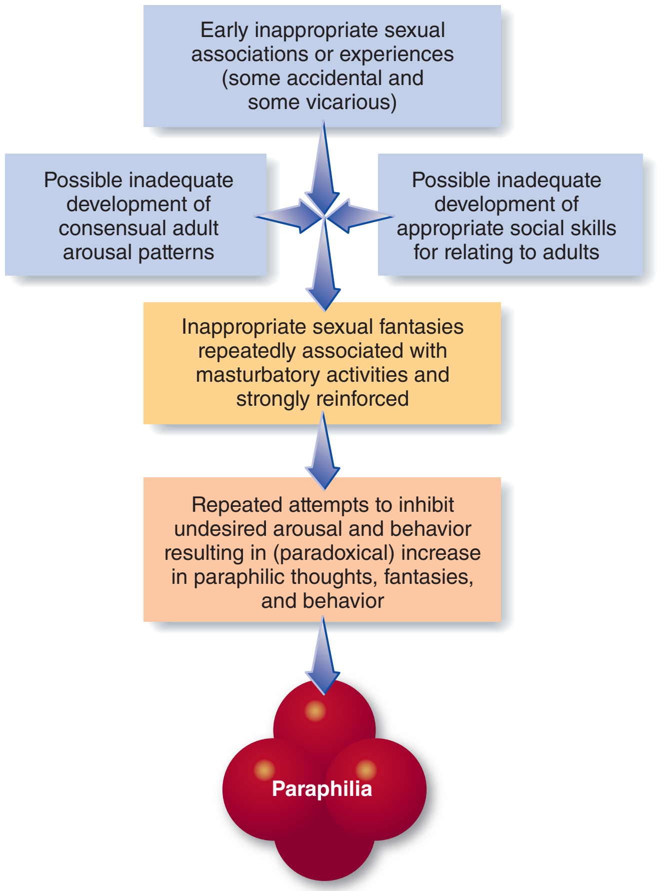
Another factor may be the nature of the person's early sexual fantasies. For example, Rachman and Hodgson (1968; see also Bancroft, 1989) demonstrated that sexual arousal could become associated with a neutral object—a boot, for example—if the boot was repeatedly presented while the individual was sexually aroused. One of the most powerful engines for developing unwanted arousal may be early sexual fantasies that are repeatedly reinforced through the strong sexual pleasure associated with masturbation (Bradford & Meston, in press). Before a pedophile or sadist ever acts on his behavior, he may fantasize about it thousands of times while masturbating. Expressed as a clinical or operant-conditioning paradigm, this is another example of a learning process in which a behavior (sexual arousal to a specific object or activity) is repeatedly reinforced through association with a pleasurable consequence (orgasm). This mechanism may explain why paraphilias are almost exclusively male disorders. The basic differences in frequency of masturbation between men and women that exist across cultures may contribute to the differential development of paraphilias. As you have seen, on rare occasions, cases of women with paraphilia do turn up (Federoff et al., 1999; Ford & Cortoni, 2008; Hunter & Mathews, 1997; Logan, 2009), and a comprehensive national study of 175 female child sexual abusers exists (Wiegel, 2008).

However, if early experiences contribute strongly to later sexual arousal patterns, then what about the Sambia males who practice exclusive homosexual behavior during childhood and early adolescence and yet are exclusively heterosexual as adults? In such cohesive societies, the social demands or "scripts" for sexual interactions are stronger and more rigid than in our culture and thus may override the effects of early experiences (Baldwin & Baldwin, 1989).

In addition, therapists and sex researchers who work with paraphilics have observed what seems to be an incredibly strong sex drive. It is not uncommon for some paraphilics to masturbate three or four times a day. In one case seen in our clinic, a sadistic rapist masturbated approximately every half hour all day long, just as often as it was physiologically possible. We have speculated elsewhere that activity this consuming may be related to the obsessional processes of obsessive-compulsive disorder (Barlow, 2002). In both instances, the very act of trying to suppress unwanted, emotionally charged thoughts and fantasies seems to have the paradoxical effect of *increasing* their frequency and intensity (see Chapter 5). This process is also ongoing in people with eating disorders and addictions, when attempts to restrict strong addictive cravings lead to uncontrollable increases in the undesired behaviors.

Psychopathologists are also becoming interested in the phenomenon of weak inhibitory control across these paraphilic disorders, which may indicate a weak biologically based behavioral inhibition system (BIS) in the brain (Fowles, 1993; Kafka, 1997; Ward & Beech, 2008) that might repress serotonergic functioning. (You may remember from Chapter 5 that the BIS is a brain circuit associated with anxiety and inhibition.)

The model shown in ■ Figure 10.8 incorporates the factors thought to contribute to the development of paraphilia. Nevertheless, all speculations, including the hypotheses we have described, have little scientific support at this time. For example, this model does not include the biological dimension. Excess arousal in paraphilics could be biologically based. Before we can make any steadfast conclusions here, more research is needed.



Early inappropriate sexual associations or experiences (some accidental and some vicarious)
Possible inadequate development of consensual adult arousal patterns
Possible inadequate development of appropriate social skills for relating to adults
Inappropriate sexual fantasies repeatedly associated with masturbatory activities and strongly reinforced
Repeated attempts to inhibit undesired arousal and behavior resulting in (paradoxical) increase in paraphilic thoughts, fantasies, and behavior
Paraphilia

■ **FIGURE 10.8** A model of the development of paraphilia.

## Assessing and Treating Paraphilia

In recent years, researchers have developed sophisticated methods for assessing specific patterns of sexual arousal (Maletzky, 1998; Wincze, 2009). This development is important in studying paraphilia because sometimes even the individual presenting with the problem is not fully aware of what caused arousal. An individual once came in complaining of uncontrollable arousal to open-toed white sandals worn by women. He noted that he was irresistibly drawn to any woman wearing such sandals and would follow her for miles. These urges occupied much of his summer. Subsequent assessment revealed that the sandal itself had no erotic value for this individual; rather, he had a strong sexual attraction to women's feet, particularly moving in a certain way.

Using the model of paraphilia described previously, we assess each patient not only for the presence of deviant arousal but also for levels of appropriate arousal to adults, for social skills, and for the ability to form relationships. Tony had no problems with social skills: he was 52 years old, reasonably happily married, and generally compatible with his second wife. His major difficulty was his continuing strong, incestuous attraction to his daughter. Nevertheless, he loved his daughter and wished strongly to interact in a normal fatherly way with her.

### Psychological Treatment

A number of treatment procedures are available for decreasing unwanted arousal. Most are behavior therapy procedures directed at changing the associations and context from arousing and pleasurable to neutral. One procedure, carried out entirely in the imagination of the patient, called **covert sensitization**, was first described by Joseph Cautela (1967; see also Barlow, 1993). In this treatment, patients associate sexually arousing images in their imagination with some reasons why the behavior is harmful or dangerous. Before treatment, the patient knows about these reasons, but the immediate pleasure and strong reinforcement the sexual activity provides is enough to overcome any thoughts of possible harm or danger that might arise in the future. This process is what happens in much unwanted addictive behavior, where the short-term pleasure outweighs the long-term harm, including bulimia.

In imagination, harmful or dangerous consequences can be associated quite directly with the unwanted behavior and arousal in a powerful and emotionally meaningful way. One of the most powerful negative aspects of Tony's behavior was his embarrassment over the thought of being discovered by his current wife, other family members, or, most important, the family priest. Therefore, he was guided through the fantasy described here.

### **TONY** *Imagining the Worst*

You are alone with your daughter in your trailer. You realize that you want to caress her breasts. So you put your arm around her, slip your hand inside her blouse, and begin to caress her breasts. Unexpectedly the door to the trailer opens and in walks your wife with Father X. Your daughter immediately jumps up and runs out the door. Your wife follows her. You are left alone with Father X. He is looking at you as if waiting for an explanation of what he has just seen. Seconds pass, but they seem like hours. You know what Father X must be thinking as he stands there staring at you. You are embarrassed and want to say something, but you can't seem to find the right words. You realize that Father X can no longer respect you as he once did. Father X finally says, "I don't understand this; this is not like you." You both begin to cry. You realize that you may have lost the love and respect of both Father X and your wife, who are important to you. Father X asks, "Do you realize what this has done to your daughter?" You think about this and you hear your daughter crying; she is hysterical. You want to run, but you can't. You are miserable and disgusted with yourself. You don't know if you will ever regain the love and respect of your wife and Father X.

■ **FIGURE 10.9** Ratings of Tony's incestuous urges (deviant) and desire for normal interactions with his daughter (nondeviant) during covert sensitization treatment. (Reproduced, with permission, from Harbert, T. L., Barlow, D. H., Hersen, M., & Austin, J. B. (1974). Measurement and modification of incestuous behavior: A case study. *Psychological Reports, 34,* 79–86, © 1974 Psychological Reports.)

During six or eight sessions, the therapist narrates such scenes dramatically, and the patient is then instructed to imagine them daily until all arousal disappears. The results of Tony's treatment are presented in ■ Figure 10.9. "Card-sort scores" are a measure of how much Tony wanted sexual interactions with his daughter in comparison with his wish for nonsexual fatherly interactions. His incestuous arousal was largely eliminated after 3 to 4 weeks, but the treatment did not affect his desire to interact with his daughter in a healthier manner. These results were confirmed by psychophysiological measurement of his arousal response. A return of some arousal at a 3-month follow-up prompted us to ask Tony if anything unusual was happening in his life. He confessed that his marriage had taken a turn for the worse and sexual relations with his wife had all but ceased. A period of marital therapy restored the therapeutic gains (see Figure 10.9). Several years later, after his daughter's therapist decided she was ready, she and Tony resumed a nonsexual relationship, which they both wanted.

Two major areas in Tony's life needed treatment: deviant (incestuous) sexual arousal and marital problems. Most individuals with paraphilic arousal patterns need a great deal of attention to family functioning or other interpersonal systems in which they operate (Barbaree & Seto, 1997; Fagan et al., 2002; Rice & Harris, 2002). In addition, many require intervention to help strengthen appropriate patterns of arousal. In **orgasmic reconditioning**, patients are instructed to masturbate to their usual fantasies but to substitute more desirable ones just before ejaculation. With repeated practice, patients should be able to begin the desired fantasy earlier in the masturbatory process and still retain their arousal. This technique, first described by Gerald Davison (1968), has been used with some success in a variety of settings (Brownell et al., 1977; Maletzky, 2002). Finally, as with most strongly pleasurable but undesirable behaviors (including addiction), care must be taken to provide the patient with coping skills to prevent slips or relapses. *Relapse prevention* treatment created for addictions (Laws, 1989; Laws & O'Donohue, 1997) does just that. Patients are taught to recognize the early signs of temptation and to institute a variety of self-control procedures before their urges become too strong.

Evidence on the effects of psychological treatments for sexual offenders is decidedly mixed at this time. For sexual offenders who have come into contact with the legal system, including those who are incarcerated (obviously a very severe group), the results are modest at best in terms of preventing later occurrences of offending (termed recidivism). Reviews of large numbers of studies with these populations are hampered because of the substantially different methods and procedures in accessing recidivism rates. But several large surveys following up sexual offenders for a period of 4 to 5 years indicate reductions in sexual recidivism (that is, reoffending) among patients who have received psychological treatments of up to 11% to 20% over what would be expected with the usual and customary treatment, with cognitive-behavioral programs proving to be the most effective in reducing recidivism (Hanson et al., 2002; Lösel & Schumacker, 2005). On the other hand, a large study from the state of California with participants who were incarcerated for their sexual offense showed very little effect of any intervention in rates of sexual or violent offending over an 8-year follow-up period after these individuals were released (Marques, Wederanders, Day, Nelson, & van Ommeren, 2005).

For outpatients, on the other hand, there is at least some evidence for success when treatment is carried out by an experienced professional. For example, Barry Maletzky, a psychiatrist at the University of Oregon Medical School, and his staff reported on the treatment of more than 8,000 sexual offenders of numerous types over 20 years (Maletzky, 2002). A variety of procedures were used in a program of 3 to 4 months in a clinic devoted exclusively to this type of treatment. What makes the report notable is that Maletzky collected objective physiological outcome measures using the penile strain gauge described earlier with almost every participant in the program, in addition to patients' reports of progress. In many cases, he also obtained corroborating information from families and legal authorities.

In his follow-up of these patients, Maletzky (2002) defined a treatment as successful when someone had (1) completed all treatment sessions, (2) demonstrated no deviant sexual arousal on objective physiological testing at any annual follow-up testing session, (3) reported no deviant arousal or behavior at any time since treatment ended, and (4) had no legal record of any charges of deviant sexual activity, even if unsubstantiated. He defined as a treatment failure anyone who was not a success. Any offender who did not complete treatment for any reason was counted as a failure, even though some may well have benefited from the partial treatment and gone on to recover. Using this criteria, from 75% to 95% of individuals, depending on the type of sexual offense (such as pedophilia, rape, or voyeurism), had a successful outcome. However, Maletzky's results were not derived from a scientifically controlled clinical trial.

Men who rape had the lowest success rate among all offenders with a single diagnosis (75%) and individuals with multiple paraphilias had the lowest success rate of any group. Maletzky (2002) also examined factors associated with failure. Among the strongest predictors were a history of unstable social relationships, an unstable employment history, strong denial the problem exists, a history of multiple victims, and a situation in which the offender continues to live with a victim (as might be typical in cases of incest). Many of these problems characterize the presumably more severe incarcerated population mentioned above.

Nevertheless, other groups using similar treatment procedures have achieved comparable success rates (Abel, 1989; Becker, 1990; Fagan et al., 2002; Pithers, Martin, & Cumming, 1989). Therapist knowledge and expertise seems to be important in successfully carrying out these treatments to prevent future sexual offenses among patients.

Judith Becker used the procedures described previously in a program for adolescent sexual offenders in an inner-city setting (see, for example, Becker, 1990; Morenz & Becker, 1995). Preliminary results indicate that a relatively low 10% of those who completed treatment had committed further sex crimes. These findings were important both because many adolescent offenders carry the AIDS virus and literally are putting their victims' lives in danger and because the recidivism rate of sexual offenders without treatment is high (see, for example, Hanson, Steffy, & Gauthier, 1993; Nagayama Hall, 1995), just as it is for all pleasurable but undesirable behavior, including substance abuse. More recently, an important study found that intervening with aggressive, victimizing, or highly inappropriate sexual behavior in children age 5 to 12 with a CBT was effective in preventing sexual offending once they reached adolescence and adulthood 10 years later compared to a group receiving play therapy (Carpentier, Silovsky, & Chaffin, 2006). Only 2% of children receiving CBT had future sexual offenses. Preventing adult sexual offending would be an important advance if these results are replicated.

## Drug Treatments

The most popular drug used to treat paraphilics is an antiandrogen called *cyproterone acetate* (Bradford, 1997; Seto, 2009). This "chemical castration" drug eliminates sexual desire and fantasy by reducing testosterone levels dramatically, but fantasies and arousal return as soon as the drug is removed. A second drug is *medroxyprogesterone* (Depo-Provera is the injectable form), a hormonal agent that reduces testosterone (Fagan et al., 2002). These drugs may be useful for dangerous sexual offenders who do not respond to alternative treatments or to temporarily suppress sexual arousal in patients who require it, but it is not always successful. In an earlier report of the Maletzky series (1991), only 8 of approximately 5,000 patients required the drug because they showed no response whatsoever to psychological treatments. Rösler and Witztum (1998) report successful "chemical castration" of 30 men with severe long-standing paraphilia using triptorelin, which inhibits gonadotropin secretion in men. This drug appears to be somewhat more effective than the other drugs mentioned here with fewer side effects, based on this one study. Of course, the drug is only effective if taken regularly, but most individuals, facing prison as the alternative, are highly motivated to comply with treatment.

## Summary

Based on evidence from a number of settings, evidence for the psychosocial treatment of paraphilia is mixed, with more success reported in outpatient settings with presumably less severe, more stable patients. But most results are uncontrolled observations from a small number of clinical research centers, and results may not be as good in other clinics and offices. In any case, as with treatment for sexual dysfunctions, psychosocial approaches to paraphilia are not readily available outside of specialized treatment centers. In the meantime, the outlook for most individuals with these disorders is bleak because paraphilias run a chronic course and recurrence is common.

## Concept Check 10.4

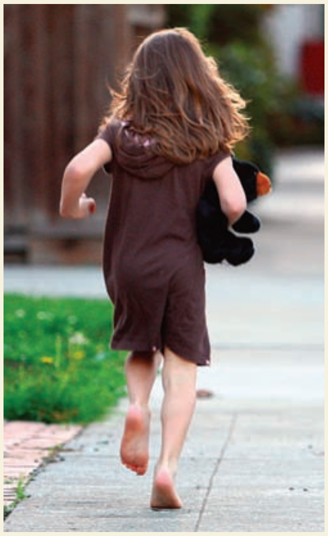
Check your understanding of sexual paraphilias by matching the scenarios with the correct label: (a) exhibitionism, (b) voyeurism, (c) fetishism, or (d) sexual masochism.

1. Mae enjoys being slapped with leather whips during foreplay. Without such stimulation, she is unable to achieve orgasm during sex. _____
2. Kai has a collection of women's panties that arouse him. He loves to look at, collect, and wear them. _____
3. Sam finds arousal in walking up to strangers in the park and showing them his genitals. _____
4. Peeping Tom loves to look through Susie's bedroom window and watch her undress. He gets extremely excited as she disrobes. He is practicing _____.
5. What Peeping Tom does not realize is that Susie knows that he is watching. She is aroused by slowly undressing while others are watching, and she fantasizes about what they are thinking. Susie's behavior is called _____.
6. What Peeping Tom will be shocked to find out is that "Susie" is actually Scott, a man who can become aroused only if he wears feminine clothing. Scott's behavior is _____.

## On the Spectrum

## Gender Nonconformity in Children and Gender Variation in Adults

Earlier in this chapter, we discussed the findings on what is now called gender nonconformity in children, and noted that long-term prospective follow-up studies indicate a complex relationship between gender nonconformity as a child and the development of gender identity, sexual orientation, or both as an adult. Briefly, findings indicate that a higher proportion of gender-nonconforming children develop a homosexual orientation as adults compared to those who are gender conforming. But most individuals with homosexual orientations as adults conform to their biological sex as children (boys act like boys and girls act like girls). It is also clear that a small minority of gender-nonconforming children are expressing a gender identity disorder in which their gender is different from their biological sex. These children will consistently identify with the opposite sex, thereby meeting diagnostic criteria for gender identity disorder in adulthood. We also reviewed research by Fausto-Sterling (2000b)—on intersexed individuals who may have some physical characteristics of the opposite sex—who surmises that both physical sex and gender identity may occur on a continuum.



©Jim Wilson/The New York Times/Redux Pictures

A question under debate is whether to refer gender-nonconforming children for interventions early on that would bring their behavior and interests more into line with their biological sex. On the one hand, some segments of society, particularly in more traditionally tolerant areas of the country such as San Francisco and New York, are becoming more open to gender variations in both children and adults. In 2006, New York City decided to let people alter the sex listed on their birth certificates, which is certainly helpful to intersexed individuals who decide to live as the gender consistent with their current identity but not the identity assigned at birth. In some schools, children are being allowed and even encouraged to dress and appear in gender-nonconforming ways on the assumption that this gives freer rein to who they "really are" (Brown, 2006). On the other hand, Skidmore and colleagues (2006) examined whether gender nonconformity was related to psychological distress in a community-based sample of gay men and lesbians. Gender nonconformity was measured by self-reports of childhood gender nonconformity, as well as ratings of current behavior. The researchers found that gender nonconformity was related to psychological distress (depression, anxiety), but only for gay men and not for lesbians.

Although only a minority of gay men report gender nonconformity as boys, research indicates that many of these gender-nonconforming boys defeminize as they reach adulthood, probably because of persistent social pressure from their family and peers. Also, interventions exist to alter gender-nonconforming behavior in young children to avoid the ostracism and scorn these children encounter in most school settings (Rekers, Kilgus, & Rosen, 1990).

Thus, society is faced with a dilemma that requires more research. Should the free expression of gender nonconformity be encouraged knowing that, in most parts of world, gender nonconformity will make for difficult social adaptation leading to substantial psychological distress for decades to come? Or will psychological adjustment be more positive if gender nonconformity is allowed and facilitated? And for intersexed individuals, rather than surgery to make individuals more physically consistent with one sex or the other, should society encourage expression along a dimension ranging from male to female, and will that be "healthier" for these individuals? If research confirms that adjustment is more positive if individuals find their own place on a gender continuum, then large-scale campaigns to alter social norms may well occur along the lines of the successful campaigns of the last several decades for gay rights, after a consensus developed in the 1970s that homosexuality was not a disorder. Research will continue on this important and interesting topic.

# Summary

### What Is Normal Sexuality?

- Patterns of sexual behavior, both heterosexual and homosexual, vary around the world in terms of both behavior and risks. Approximately 20% of individuals who have been surveyed engage in sex with numerous partners, which puts them at risk for sexually transmitted diseases such as AIDS. Recent surveys also suggest that as many as 60% of American college females practice unsafe sex by not using condoms.
- Three types of disorders are associated with sexual functioning and gender identity: gender identity disorder, sexual dysfunctions, and paraphilias.

### Gender Identity Disorder

- Gender identify disorder is a dissatisfaction with one's biological sex and the sense that one is really the opposite gender (for example, a woman trapped in a man's body). A person develops gender identity between 18 months and 3 years of age, and it seems that both appropriate gender identity and mistaken gender identity have biological roots influenced by learning.
- Treatment for adults may include sex reassignment surgery integrated with psychological approaches.

### Overview of Sexual Dysfunctions

- Sexual dysfunction includes a variety of disorders in which people find it difficult to function adequately during sexual relations.
- Specific sexual dysfunctions include disorders of sexual desire (hypoactive sexual desire disorder and sexual aversion disorder) in which interest in sexual relations is extremely low or nonexistent; disorders of sexual arousal (male erectile disorder and female sexual arousal disorder) in which achieving or maintaining adequate penile erection or vaginal lubrication is problematic; and orgasmic disorders (female orgasmic disorder and male orgasmic disorder) in which orgasm occurs too quickly or not at all. The most common disorder in this category is premature ejaculation, which occurs in males; inhibited orgasm is commonly seen in females.
- Sexual pain disorders, in which unbearable pain is associated with sexual relations, include dyspareunia and vaginismus.

### Assessing Sexual Behavior

- The three components of assessment are interviews, a complete medical evaluation, and psychophysiological assessment.

### Causes and Treatment of Sexual Dysfunction

- Sexual dysfunction is associated with socially transmitted negative attitudes about sex, current relationship difficulties, and anxiety focused on sexual activity.
- Psychosocial treatment of sexual dysfunctions is generally successful but not readily available. In recent years, various medical approaches have become available, including the drug Viagra. These treatments focus mostly on male erectile dysfunction and are promising.

### Paraphilia: Clinical Descriptions

- Paraphilia is sexual attraction to inappropriate people, such as children, or to inappropriate objects, such as articles of clothing.
- The paraphilias include fetishism, in which sexual arousal occurs almost exclusively in the context of inappropriate objects or individuals; exhibitionism, in which sexual gratification is attained by exposing one's genitals to unsuspecting strangers; voyeurism, in which sexual arousal is derived from observing unsuspecting individuals undressing or naked; transvestic fetishism, in which individuals are sexually aroused by wearing clothing of the opposite sex; sexual sadism, in which sexual arousal is associated with inflicting pain or humiliation; sexual masochism, in which sexual arousal is associated with experiencing pain or humiliation; and pedophilia, in which there is a strong sexual attraction toward children. Incest is a type of pedophilia in which the victim is related, often a son or daughter.
- The development of paraphilia is associated with deficiencies in consensual adult sexual arousal, deficiencies in consensual adult social skills, deviant sexual fantasies that may develop before or during puberty, and attempts by the individual to suppress thoughts associated with these arousal patterns.

### Assessing and Treating Paraphilia

- Psychosocial treatments of paraphilia are only modestly effective at best among individuals who are incarcerated, but somewhat more successful in less severe outpatients.

## Answers to Concept Checks

### 10.1

**1.** More men masturbate and do it more often; men are more permissive about casual sex; women want more intimacy from sex, and so on.
**2.** Both heterosexuality and homosexuality are normal; genetics appear to play some role in the development of sexual preference.
**3.** Gender identity disorder
**4.** Abnormal hormone levels during development, social or parental influences
**5.** Sex reassignment surgery, psychosocial treatment to adjust to either gender

### 10.2

**1.** c; **2.** a; **3.** b; **4.** c; **5.** a

### 10.3

**1.** T; **2.** F (sometimes increases arousal); **3.** T; **4.** T; **5.** F (nondemand pleasuring, squeeze technique, and so on); **6.** T

### 10.4

**1.** d; **2.** c; **3.** a; **4.** b; **5.** a; **6.** c

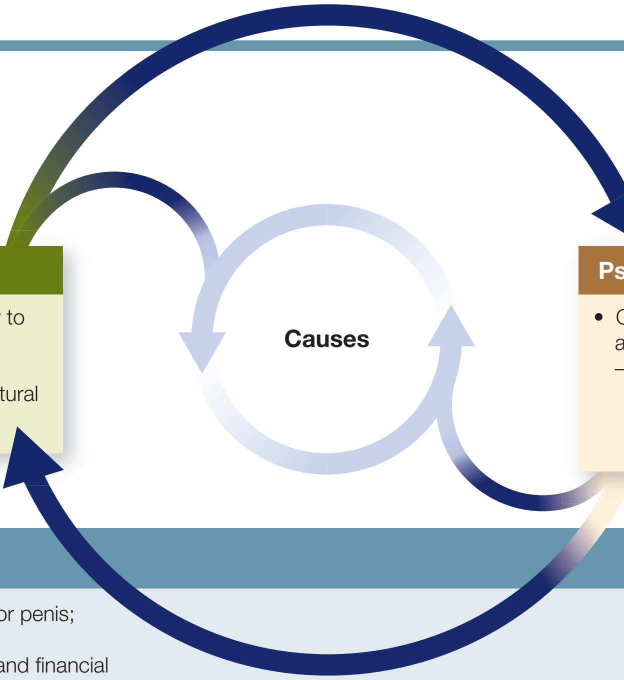
- Premature Ejaculation
- Sexual Pain Disorders (Dyspareunia)
- Vaginismus
- Paraphilias

# Exploring Sexual and Gender Identity Disorders

- Sexual behavior is considered normal in our culture unless it is associated with one of three kinds of impaired functioning—gender identity disorder, sexual dysfunction, or paraphilia.
- Sexual orientation probably has a strong biological basis that is influenced by environmental and social factors.

## GENDER IDENTITY DISORDERS

Present when a person feels trapped in a body that is the "wrong" sex, that does not match his or her innate sense of personal identity. (Gender identity is independent of sexual arousal patterns.) Relatively rare.



©Thinkstock/Getty Images

### Biological Influences

- Not yet confirmed, although likely to involve prenatal exposure to hormones
  - Hormonal variations may be natural or result from medication

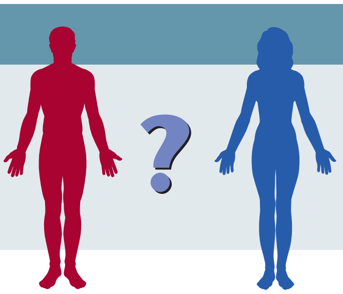
**Causes**

### Psychological Influences

- Gender identity develops between $1\frac{1}{2}$ and 3 years of age
  - "Masculine" behaviors in girls and "feminine" behaviors in boys evoke different responses in different families

### Treatment

- Sex reassignment surgery: removal of breasts or penis; genital reconstruction
  - Requires rigorous psychological preparation and financial and social stability
- Psychosocial intervention to change gender identity
  - Usually unsuccessful except as temporary relief until surgery



## PARAPHILIAS

Sexual arousal occurs almost exclusively in the context of inappropriate objects or individuals.

### Types

- ***Fetishism:*** Sexual attraction to nonliving objects
- ***Voyeurism:*** Sexual arousal achieved by viewing unsuspecting person undressing or naked
- ***Exhibitionism:*** Sexual gratification from exposing one's genitals to unsuspecting strangers
- ***Transvestite fetishism:*** Sexual arousal from wearing opposite-sex clothing (cross-dressing)
- ***Sexual sadism:*** Sexual arousal associated with inflicting pain or humiliation
- ***Sexual masochism:*** Sexual arousal associated with experiencing pain or humiliation
- ***Pedophilia:*** Strong sexual attraction to children
- ***Incest:*** Sexual attraction to family member

©PhotoDisc/Getty Images

### Causes

- Preexisting deficiencies
  - In levels of arousal with consensual adults
  - In consensual adult social skills
- Treatment received from adults during childhood
- Early sexual fantasies reinforced by masturbation
- Extremely strong sex drive combined with uncontrollable thought processes

©Thinkstock/Getty Images

### Treatment

- *Covert sensitization:* Repeated mental reviewing of aversive consequences to establish negative associations with behavior
- *Relapse prevention:* Therapeutic preparation for coping with future situations
- *Orgasmic reconditioning:* Pairing appropriate stimuli with masturbation to create positive arousal patterns
- *Medical:* Drugs that reduce testosterone to suppress sexual desire; fantasies and arousal return when drugs are stopped

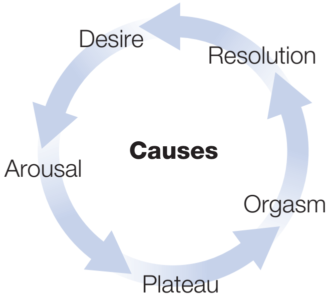
©PhotoDisc/Getty Images

## SEXUAL DYSFUNCTIONS

Sexual dysfunctions can be
- ***Lifelong:*** Present during entire sexual history
- ***Acquired:*** Interrupts normal sexual pattern
- ***Generalized:*** Present in every encounter
- ***Situational:*** Present only with certain partners or at certain times

### The Human Sexual Response Cycle

A dysfunction is an impairment in one of the sexual response stages.



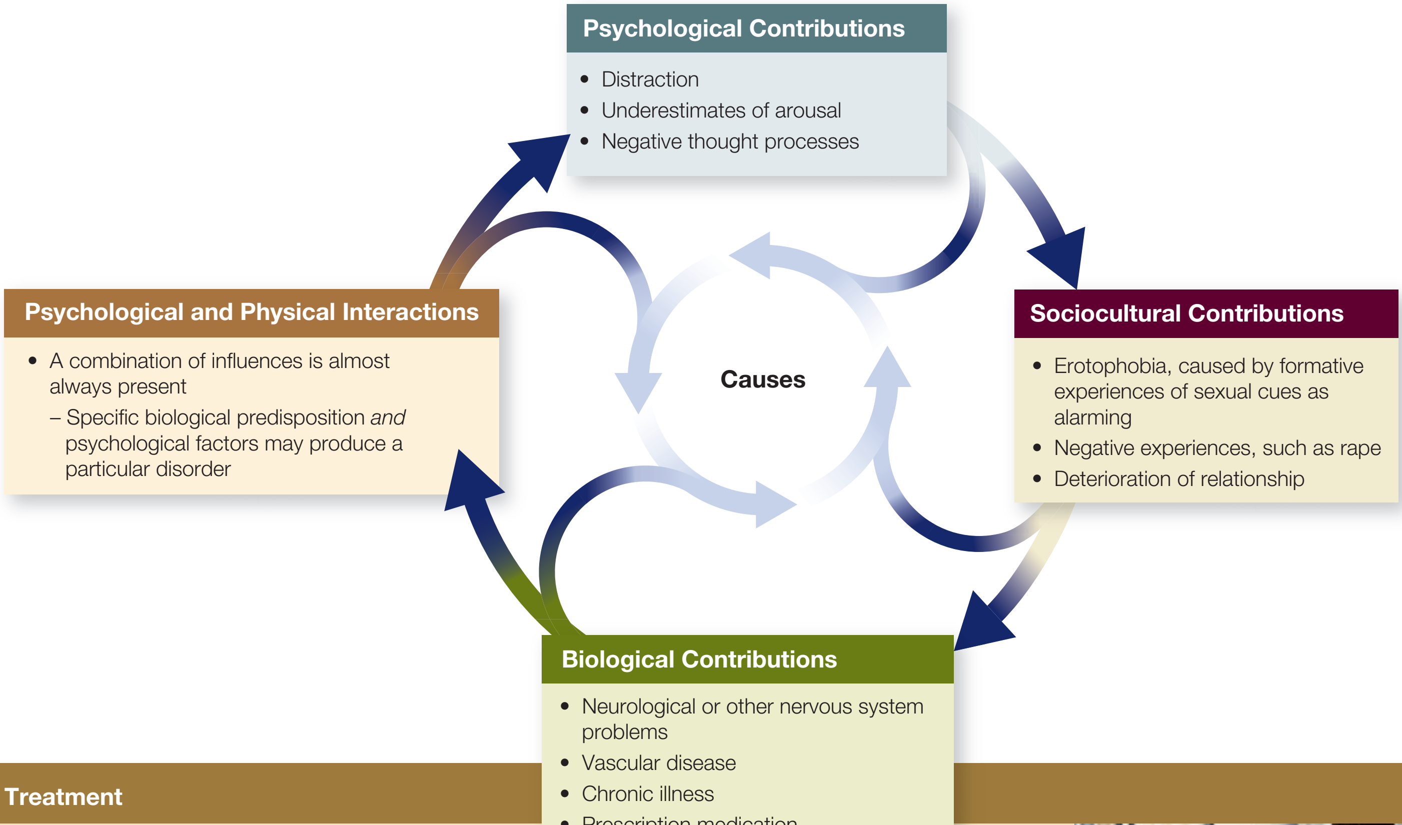
### Types of Sexual Dysfunctions

**Sexual Desire Disorders**
- ***Hypoactive sexual desire disorder:*** Apparent lack of interest in sexual activity or fantasy
- ***Sexual aversion disorder:*** Extreme persistent dislike of sexual contact

**Sexual Arousal Disorders**
- ***Male erectile disorder:*** Recurring inability to achieve or maintain adequate erection
- ***Female sexual arousal disorder:*** Recurring inability to achieve or maintain adequate lubrication

**Orgasm Disorders**
- ***Inhibited orgasm:*** Inability to achieve orgasm despite adequate desire and arousal
- ***Premature ejaculation:*** Ejaculation before it is desired, with minimal stimulation

**Sexual Pain Disorders**
- ***Dyspareunia:*** Marked pain associated with intercourse for which there is no medical cause; occurs in males and females
- ***Vaginismus:*** Involuntary muscle spasms in the front of the vagina that prevent or interfere with intercourse



### Psychological Contributions

- Distraction
- Underestimates of arousal
- Negative thought processes

**Causes**

### Sociocultural Contributions

- Erotophobia, caused by formative experiences of sexual cues as alarming
- Negative experiences, such as rape
- Deterioration of relationship

### Biological Contributions

- Neurological or other nervous system problems
- Vascular disease
- Chronic illness
- Prescription medication
- Drugs of abuse, including alcohol

### Psychological and Physical Interactions

- A combination of influences is almost always present
  - – Specific biological predisposition *and* psychological factors may produce a particular disorder

### Treatment

- *Psychosocial:* Therapeutic program to facilitate communication, improve sexual education, and eliminate anxiety. Both partners participate fully.
- *Medical:* Almost all interventions focus on male erectile disorder, including drugs, prostheses, and surgery. Medical treatment is combined with sexual education and therapy to achieve maximum benefit.

## STUDENT LEARNING OUTCOMES*

| | |
|---|---|
| Demonstrate knowledge and understanding representing appropriate breadth and depth in selected content areas of psychology: | › Biological bases of behavior and mental processes, including physiology, sensation, perception, comparative, motivation, and emotion (APA SLO 1.2.a (3)) ***(see textbook pages 395–397, 411–412, 419–420)*** |
| Use the concepts, language, and major theories of the discipline to account for psychological phenomena. | › Describe behavior and mental processes empirically, including operational definitions (APA SLO 1.3.a) ***(see textbook pages 392–412, 424–426)*** |
| Identify appropriate applications of psychology in solving problems, such as: | › Origin and treatment of abnormal behavior (APA SLO 4.2.b) ***(see textbook pages 412–424)*** |

---

* Portions of this chapter cover learning outcomes suggested by the American Psychological Association (2007) in their guidelines for the undergraduate psychology major. Chapter coverage of these outcomes is identified above by APA Goal and APA Suggested Learning Outcome (SLO).

Would you be surprised if we told you that a group of psychological disorders costs U.S. citizens hundreds of billions of dollars each year, kills 500,000 Americans annually, and is implicated in street crime, homelessness, and gang violence? Would you be even more surprised to learn that most of us have behaved in ways characteristic of these disorders at some point in our lives? You shouldn't. Smoking cigarettes, drinking alcohol, and using illegal drugs are all related to these disorders, and they are responsible for astronomical financial costs and the tragic waste of hundreds of thousands of human lives each year. In this chapter, we explore **substance-related disorders**, which are associated with the abuse of drugs such as alcohol, cocaine, and heroin and with a variety of other substances people take to alter the way they think, feel, and behave. These disorders represent a problem that has cursed us for centuries and continues to affect how we live, work, and play.

Equally disruptive to the people affected, **impulse-control disorders** represent a number of related problems that involve the inability to resist acting on a drive or temptation. Included in this group are those who cannot resist aggressive impulses or the impulse to steal, to set fires, to gamble, or, for some, to pull out their own hair. Controversy surrounds both substance-related and impulse-control disorders because our society sometimes believes that these problems result simply from a lack of "will." If you wanted to stop drinking, using cocaine, or gambling, well, you would just stop. We first examine those individuals who are being harmed by their use of a variety of chemical substances (substance-related disorders) and then turn our attention to the puzzling array of disorders that are under the heading of impulse-control disorders.

## Perspectives on Substance-Related Disorders

The cost in lives, money, and emotional turmoil has made the issue of drug abuse a major concern worldwide. Currently, more than 8% of the general population is believed to use illegal drugs (Substance Abuse and Mental Health Services Administration, 2009). Many U.S. presidential administrations have declared various "wars on drugs," but the problem remains. The Roman Catholic Church issued a universal catechism in 1992 that officially declared drug abuse and drunk driving to be sins (Riding, 1992). Yet from the drug-related deaths of rock stars Jimi Hendrix and Janis Joplin in 1970 to contemporary celebrities such as Michael Jackson and Heath Ledger, drug use continues to negatively impact the lives of many. And stories such as these not only are about the rich and famous but are retold in every corner of our society.

As we have just seen, a significant number of people continue to use illicit drugs and abuse prescription drugs regularly. Consider the case of Danny, who has the disturbing but common habit of **polysubstance use**, using multiple substances. (We cover this issue in more detail later in the chapter.)

### DANNY | *Multiple Dependencies*

At the age of 43, Danny was in jail, awaiting trial on vehicular manslaughter charges stemming from a DWI accident that left one woman dead. Danny's story illustrates the lifelong pattern that characterizes the behavior of many people who are affected by substance-related disorders.

Danny grew up in the suburban United States, the youngest of three children. He was well liked in school and an average student. Like many of his friends, he smoked cigarettes in his early teens and drank beer with his friends at night behind his high school. Unlike most of his friends, however, Danny almost always drank until he was obviously drunk; he also experimented with many other drugs, including cocaine, heroin, "speed" (amphetamines), and "downers" (barbiturates).

After high school, Danny attended a local community college for one semester, but he dropped out after failing most of his courses. His dismal performance in school seemed to be related to his missing most classes rather than to an inability to learn and understand the material. He had difficulty getting up for classes after partying most of the night, which he did with increasing frequency. His moods were highly variable, and he was often unpleasant. Danny's family knew he occasionally drank too much, but they didn't know (or didn't want to know) about his other drug use. He had for years forbidden anyone to go into his room after his mother found little packets of white powder (probably cocaine) in his sock drawer. He said he was keeping them for a friend and that he would return them immediately. He was furious that his family might suspect him of using drugs. Money was sometimes missing from the house, and once some stereo equipment "disappeared," but if his family members suspected Danny they never admitted it.

Danny held a series of low-paying jobs, and when he was working his family reassured themselves that he was back on track and things would be fine. Unfortunately, he rarely held a job for more than a few months. The money he earned had a magical way of turning into drugs, and he was usually fired for poor job attendance and performance. Because he continued to live at home, Danny could survive despite frequent periods of unemployment. When he was in his late 20s, Danny seemed to have a personal revelation. He announced that he needed help and planned to check into an alcohol rehabilitation center; he still would not admit to using other drugs. His family's joy and relief were overwhelming, and no one questioned his request for several thousand dollars to help pay for the private program he said he wanted to attend. Danny disappeared for several weeks, presumably because he was in the rehabilitation program. However, a call from the local police station put an end to this fantasy: Danny had been found quite high, living in an abandoned building. As with many of these incidents, we never learned all the details, but it appears that Danny spent his family's money on drugs and had a 3-week binge with some friends. Danny's deceptiveness and financial irresponsibility greatly strained his relationship with his family. He was allowed to continue living at home, but his parents and siblings excluded him from their emotional lives. Danny seemed to straighten out, and he held a job at a gas station for almost 2 years. He became friendly with the station owner and his son, and he often went hunting with them during the season. However, without any obvious warning, Danny resumed drinking and using drugs and was arrested for robbing the very place that had kept him employed for many months.

Although he received probation for that offense upon promising to attend drug treatment, his pattern continued. Years later while driving under the influence of multiple substances, he hit another car and the 28-year-old driver of that car was killed.

Why did Danny become dependent on drugs when many of his friends and siblings did not? Why did he steal from his family and friends? What ultimately became of him? We return to Danny's frustrating story later when we look at the causes and treatment of substance-related disorders.

## Levels of Involvement

Although each drug described in this chapter has unique effects, there are similarities in the ways they are used and how people who abuse them are treated. We first survey some concepts that apply to substance-related disorders in general, noting important terminology and addressing several diagnostic issues.

Can you use drugs and not abuse them? Can you abuse drugs and not become addicted to them? To answer these important questions, we first need to outline what we mean by *substance use, substance intoxication, substance abuse,* and *dependence.* The term *substance* refers to chemical compounds that are ingested to alter mood or behavior. Although you might first think of drugs such as cocaine and heroin, this definition also includes more commonplace legal drugs such as alcohol, the nicotine found in tobacco, and the caffeine in coffee, soft drinks, and chocolate. As you will see, these so-called safe drugs also affect mood and behavior, they can be addictive, and they account for more health problems and a greater mortality rate than all illegal drugs combined. You could make a good argument for directing the war on drugs to cigarette smoking (nicotine use) because of its addictive properties and negative health consequences.

To understand substance-related disorders, we must first know what it means to ingest **psychoactive substances**—which alter mood, behavior, or both—to become intoxicated or high, to abuse these substances, and to become dependent on or addicted to them.

### Substance Use

Substance use is the ingestion of psychoactive substances in moderate amounts that does not significantly interfere with social, educational, or occupational functioning. Most of you reading

©Ariel Skelley/Blend Images/Jupiter Images

▲ Substance use.

this chapter probably use some sort of psychoactive substance occasionally. Drinking a cup of coffee in the morning to wake up or smoking a cigarette and having a drink with a friend to relax are examples of substance use, as is the occasional ingestion of illegal drugs such as marijuana, cocaine, amphetamines, or barbiturates.

### Intoxication

Our physiological reaction to ingested substances—drunkenness or getting high—is referred to as **substance intoxication**. For a person to become intoxicated depends on which drug is taken, how much is ingested, and the person's individual biological reaction. For many of the substances we discuss here, intoxication is experienced as impaired judgment, mood changes, and lowered motor ability (for example, problems walking or talking).

#### DSM-IV-TR **Table 11.1** Diagnostic Criteria for Substance Intoxication

**A.** The development of a reversible substance-specific syndrome due to recent ingestion of (or exposure to) a substance. *Note:* Different substances may produce similar or identical syndromes.

**B.** Clinically significant maladaptive behavioral or psychological changes that are due to the effect of the substance on the central nervous system (e.g., belligerence, mood lability, cognitive impairment, impaired judgment, impaired social or occupational functioning) and develop during or shortly after use of the substance.

**C.** The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder.

*Source:* Reprinted with permission, from American Psychiatric Association. (2000). *Diagnostic and statistical manual of mental disorders* (4th ed., text revision). Washington, DC: Author, © 2000 American Psychiatric Association.

### Substance Abuse

Defining **substance abuse** by how much of a substance is ingested is problematic. For example, is drinking two glasses of wine in an hour abuse? Three glasses? Six? Is taking one injection of heroin considered abuse? The fourth edition, text revision, of the *Diagnostic and Statistical Manual (DSM-IV-TR)* (American Psychiatric Association, 2000) defines substance abuse in terms of how significantly it interferes with the user's life. If substances disrupt your education, job, or relationships with others, and put you in physically dangerous situations (for example, while driving), and if you have related legal problems, you would be considered a drug abuser. Some evidence suggests that high school drug use can predict later job outcomes. In one study, researchers controlled for factors such as educational interests and other problem behavior, and still found that repeated hard drug use (using one or more of the following: amphetamines, barbiturates, crack, cocaine, PCP, LSD, other psychedelics, crystal meth, inhalants, heroin, or other narcotics) predicted poor job outcomes at age 29 (Ringel, Ellickson, & Collins, 2007).

Danny seems to fit this definition of abuse. His inability to complete a semester of community college was a direct result of drug use. Danny often drove while drunk or under the influence

#### DSM-IV-TR **Table 11.2** Diagnostic Criteria for Substance Abuse

**A.** A maladaptive pattern of substance use leading to clinically significant impairment or distress, as manifested by one (or more) of the following, during the same 12-month period:

1. Recurrent substance use resulting in a failure to fulfill major role obligations at work, school, or home (e.g., repeated absences or poor work performance related to substance use; substance-related absences, suspensions, or expulsions from school; neglect of children or household)
2. Recurrent substance use in situations in which it is physically hazardous (e.g., driving an automobile or operating a machine when impaired by substance use)
3. Recurrent substance-related legal problems (e.g., arrests for substance-related disorderly conduct)
4. Continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance (e.g., arguments with spouse about consequences of intoxication, physical fights)

**B.** The symptoms have never met the criteria for substance dependence for this class of substance.

*Source:* Reprinted with permission, from American Psychiatric Association. (2000). *Diagnostic and statistical manual of mental disorders* (4th ed., text revision). Washington, DC: Author, © 2000 American Psychiatric Association.

©Andrew Hobbs/Stone/Getty Images

▲ Intoxication.

of other drugs, and he had already been arrested twice. Danny's use of multiple substances was so relentless and pervasive that he would probably be diagnosed as drug dependent, which indicates a severe form of the disorder.

### Substance Dependence

Drug dependence is usually described as addiction. Although we use the term *addiction* routinely when we describe people who seem to be under the control of drugs, there is some disagreement about how to define addiction, or **substance dependence** (Strain, 2009). In one definition, the person is physiologically dependent on the drug or drugs, requires increasingly greater amounts of the drug to experience the same effect (**tolerance**), and will respond physically in a negative way when the substance is no longer ingested (**withdrawal**) (American Psychiatric Association, 2007). Tolerance and withdrawal are physiological reactions to the chemicals being ingested. How many of you have experienced headaches when you didn't get your morning coffee? You were probably going through caffeine withdrawal. In a more extreme example, withdrawal from alcohol can cause alcohol withdrawal delirium, in which a person can experience frightening hallucinations and body tremors (a condition described later in this chapter). Withdrawal from many substances can bring on chills, fever, diarrhea, nausea and vomiting, and aches and pains. However, not all substances are physiologically addicting. For example, you do not go through severe physical withdrawal when you stop taking LSD. Cocaine withdrawal has a pattern that includes anxiety, lack of motivation, and boredom (Leamon, Wright, & Myrick, 2008), and withdrawal from marijuana includes such symptoms as nervousness, appetite change, and sleep disturbance (Ehlers et al., 2010). In fact, although previously believed not to be a problem, marijuana (cannabis) withdrawal is now being considered for inclusion in the *DSM-5* (Martin, Chung, & Langenbucher, 2008). We return to the ways drugs act on our bodies when we examine the causes of abuse and dependence.

Another view of substance dependence uses the "drug-seeking behaviors" themselves as a measure of dependence. The repeated use of a drug, a desperate need to ingest more of the substance (stealing money to buy drugs, standing outside in the cold to smoke), and the likelihood that use will resume after a period of abstinence are behaviors that define the extent of drug dependence. Such behavioral reactions are different from the physiological responses to drugs we described before and are sometimes referred to in terms of psychological dependence. The *DSM-IV-TR* definition of substance dependence combines the physiological aspects of tolerance and withdrawal with their behavioral and psychological aspects (American Psychiatric Association, 2000c).

This definition of dependence must be seen as a "work in progress." By these criteria, many people can be considered dependent on such activities as sex, work, or even eating chocolate. What most peo-

#### DSM-IV-TR **Table 11.3** Diagnostic Criteria for Substance Dependence

A maladaptive pattern of substance use, leading to clinically significant impairment or distress, as manifested by three (or more) of the following, occurring at any time in the same 12-month period:

**1.** Tolerance, as defined by either of the following:
   **a.** A need for markedly increased amounts of the substance to achieve intoxication or desired effect
   **b.** Markedly diminished effect with continued use of the same amount of the substance
**2.** Withdrawal, as manifested by either of the following:
   **a.** The characteristic withdrawal syndrome for the substance (refer to criteria A and B of the criteria sets for withdrawal from the specific substances)
   **b.** The same (or a closely related) substance is taken to relieve or avoid withdrawal symptoms
**3.** The substance is often taken in larger amounts or over a longer period than was intended
**4.** There is a persistent desire or unsuccessful efforts to cut down or control substance use
**5.** A great deal of time is spent in activities necessary to obtain the substance (e.g., visiting multiple doctors or driving long distances), use the substance (e.g., chain-smoking), or recover from its effects
**6.** Important social, occupational, or recreational activities are given up or reduced because of substance use
**7.** The substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance (e.g., current cocaine use despite recognition of cocaine-induced depression, or continued drinking despite recognition that an ulcer was made worse by alcohol consumption)

Specify if:

With physiological dependence: Evidence of tolerance or withdrawal (i.e., either item 1 or 2 is present)

Without physiological dependence: No evidence of tolerance or withdrawal (i.e., neither item 1 nor 2 is present)

©ACE STOCK LIMITED/Alamy

▲ Substance abuse.

ple consider serious addiction to drugs is qualitatively different from dependence on shopping or television. The physiological and behavioral patterns may need to be further refined before we can separate the truly serious phenomenon of substance dependence from less debilitating so-called addictions.

Let's go back to the questions we started with: "Can you use drugs and not abuse them?" and "Can you abuse drugs and not become addicted to or dependent on them?" The answer to the first question is yes. Some people drink wine or beer regularly without drinking to excess. Although it is not commonly believed, some people use drugs such as heroin, cocaine, or crack (a form of cocaine) occasionally (for instance, several times a year) without abusing them (Goldman & Rather, 1993). What is disturbing is that we do not know ahead of time who might be likely to lose control and abuse these drugs and who is likely to become dependent with even a passing use of a substance.

It may seem counterintuitive, but dependence can be present without abuse. For example, cancer patients who take morphine for pain may become dependent on the drug—build up a tolerance and go through withdrawal if it is stopped—without abusing it (Portenoy & Mathur, 2009). Later in this chapter, we discuss biological and psychosocial theories of the causes of substance-related disorders and of why we have individualized reactions to these substances.

Experts in the substance use field were asked about the relative "addictiveness" of various drugs (Franklin, 1990). The survey results are shown in ■ Figure 11.1. You may be surprised to see nicotine placed just ahead of methamphetamine and crack cocaine as the most addictive of drugs. Although this is only a subjective rating by these experts, it shows that our society sanctions or forbids drugs based on factors other than their addictiveness.

## Diagnostic Issues

In early editions of the *DSM,* alcoholism and drug abuse weren't treated as separate disorders. Instead, they were categorized as "sociopathic personality disturbances" (a forerunner of the current *antisocial personality disorder,* which we discuss in Chapter 12), because substance use was seen as a symptom of other problems. It was considered a sign of moral weakness, and the influence of genetics and biology was hardly acknowledged. A separate category was created for substance abuse disorders in *DSM-III,* in 1980, and since then we have acknowledged the complex biological and psychological nature of the problem.

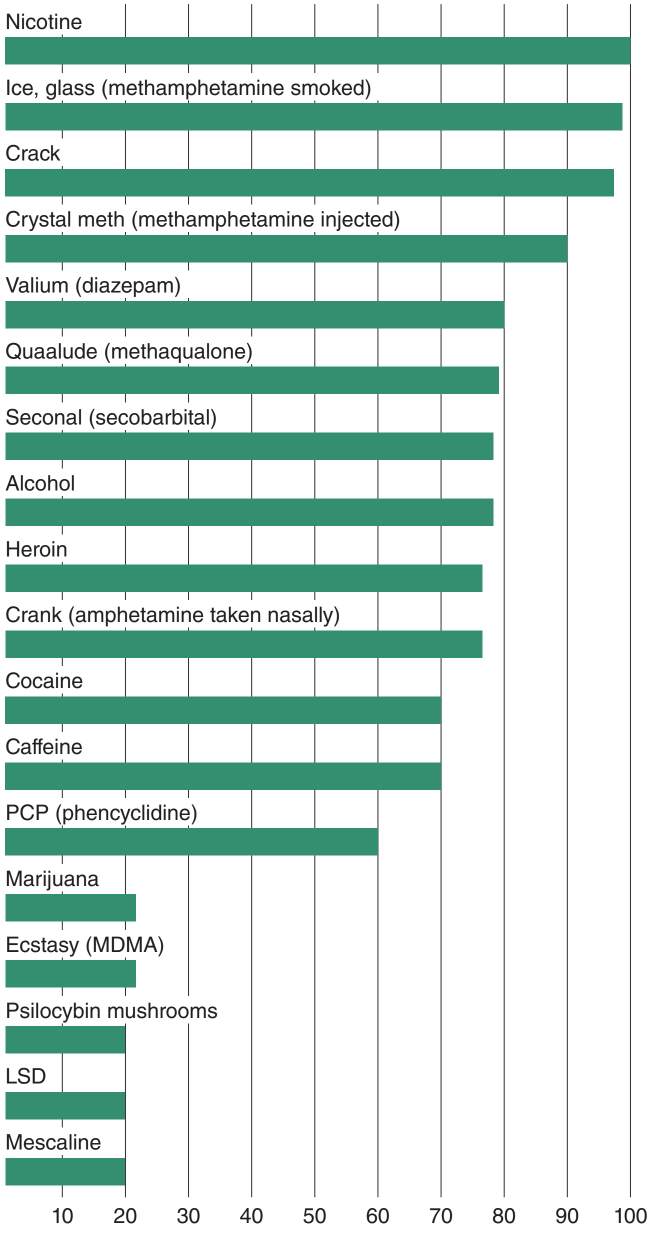
The *DSM-IV-TR* term *substance-related disorders* indicates several subtypes of diagnoses for each substance, including dependence, abuse, intoxication, withdrawal, or a combination of these. These distinctions help clarify the problem and focus treatment on the appropriate aspect of the disorder. Danny received the diagnosis "cocaine dependence" because of the tolerance he showed for the drug, his use of larger amounts than he intended, his unsuccessful attempts to stop using it, and the activities he gave up to buy it. His pattern of use was more pervasive than simple abuse, and the diagnosis of dependence provided a clear picture of his need for help.

Symptoms of other disorders can complicate the substance abuse picture significantly. For example, do some people take drugs to excess because they are depressed, or does drug use and its consequences (for example, loss of friends, job) create depression? Researchers estimate that almost three quarters of the people in addiction treatment centers have an additional psychiatric disorder, with mood disorders (such as major depression) observed in more than 40% and anxiety disorders and posttraumatic stress disorder seen in more than 25% of the cases (McGovern, Xie, Segal, Siembab, & Drake, 2006).

Substance use might occur concurrently with other disorders for several reasons (Strain, 2009). Substance-related disorders and anxiety and mood disorders are highly prevalent in our society and may occur together so often just by chance. Drug intoxication and withdrawal can cause symptoms of anxiety, depression, and psychosis. Disorders such as schizophrenia and antisocial personality disorder are highly likely to include a secondary problem of substance use.

Because substance-related disorders can be so complicated, the *DSM-IV-TR* tries to define when a symptom is a result of substance use and when it is not. Basically, if symptoms seen in schizophrenia or in extreme states of anxiety appear during intoxication or within 6 weeks after withdrawal from drugs, they aren't considered signs of a separate psychiatric disorder.

**TO RANK** today's commonly used drugs by their addictiveness, experts were asked to consider two questions: How easy is it to get hooked on these substances, and how hard is it to stop using them? Although a person's vulnerability to a drug also depends on individual traits—physiology, psychology, and social and economic pressures—these rankings reflect only the addictive potential inherent in the drug. The numbers are relative rankings, based on the experts' scores for each substance.



Research by John Hastings.

■ **FIGURE 11.1** Easy to get hooked on, hard to get off. (Reprinted, with permission, from Hastings, J. (1990). November/December. Easy to get hooked on, hard to get off. *In Health,* p. 37, © 1990 In Health.)

So, for example, individuals who show signs of severe depression just after they have stopped taking heavy doses of stimulants would not be diagnosed with a major mood disorder. However, individuals who were severely depressed before they used stimulants and those whose symptoms persist more than 6 weeks after they stop might have a separate disorder (Leamon et al., 2008).

We now turn to the individual substances themselves, their effects on our brains and bodies, and how they are used in our society. We have grouped the substances into five general categories.

- **Depressants**: These substances result in behavioral sedation and can induce relaxation. They include alcohol (ethyl alcohol) and the sedative, hypnotic, and anxiolytic drugs in the families of barbiturates (for example, Seconal) and benzodiazepines (for example, Valium, Xanax).
- **Stimulants**: These substances cause us to be more active and alert and can elevate mood. Included in this group are amphetamines, cocaine, nicotine, and caffeine.
- **Opiates**: The major effect of these substances is to produce analgesia temporarily (reduce pain) and euphoria. Heroin, opium, codeine, and morphine are included in this group.
- **Hallucinogens**: These substances alter sensory perception and can produce delusions, paranoia, and hallucinations. Marijuana and LSD are included in this category.
- **Other Drugs of Abuse**: Other substances that are abused but do not fit neatly into one of the categories here include inhalants (for example, airplane glue), anabolic steroids, and other over-the-counter and prescription medications (for example, nitrous oxide). These substances produce a variety of psychoactive effects that are characteristic of the substances described in the previous categories.

## Depressants

Depressants primarily *decrease* central nervous system activity. Their principal effect is to reduce our levels of physiological arousal and help us relax. Included in this group are alcohol and the sedative, hypnotic, and anxiolytic drugs, such as those prescribed for insomnia (see Chapter 8). These substances are among those most likely to produce symptoms of physical dependence, tolerance, and withdrawal. We first look at the most commonly used of these substances—alcohol—and the **alcohol use disorders** that can result.

### Alcohol Use Disorders

Danny's substance abuse began when he drank beer with friends, a rite of passage for many teenagers. Alcohol has been widely used throughout history. For example, scientists have found evidence of wine or beer in pottery jars at the site of a Sumerian trading post in western Iran and in Soviet Georgia that date back 7,000 years (McGovern, 2007). For hundreds of years, Europeans drank large amounts of beer, wine, and hard liquor. When they came to North America in the early 1600s, they brought their considerable thirst for alcohol with them. In the United States during the early 1800s, consumption of alcohol (mostly whiskey) was more than 7 gallons per year for every person older than 15. This is more than three times the current rate of U.S. alcohol use (Goodwin & Gabrielli, 1997; Rorabaugh, 1991).

Alcohol is produced when certain yeasts react with sugar and water and *fermentation* takes place. Historically, we have been

### DSM-IV-TR **Table 11.4** Diagnostic Criteria for Alcohol Intoxication

**A.** Recent ingestion of alcohol.

**B.** Clinically significant maladaptive behavioral or psychological changes (e.g., inappropriate sexual or aggressive behavior, mood lability, impaired judgment, impaired social or occupational functioning) that developed during, or shortly after, alcohol use.

**C.** One or more of the following signs, developing during, or shortly after, alcohol use:

1. Slurred speech
2. Incoordination
3. Unsteady gait
4. Nystagmus
5. Impairment in attention or memory
6. Stupor or coma

**D.** The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder.

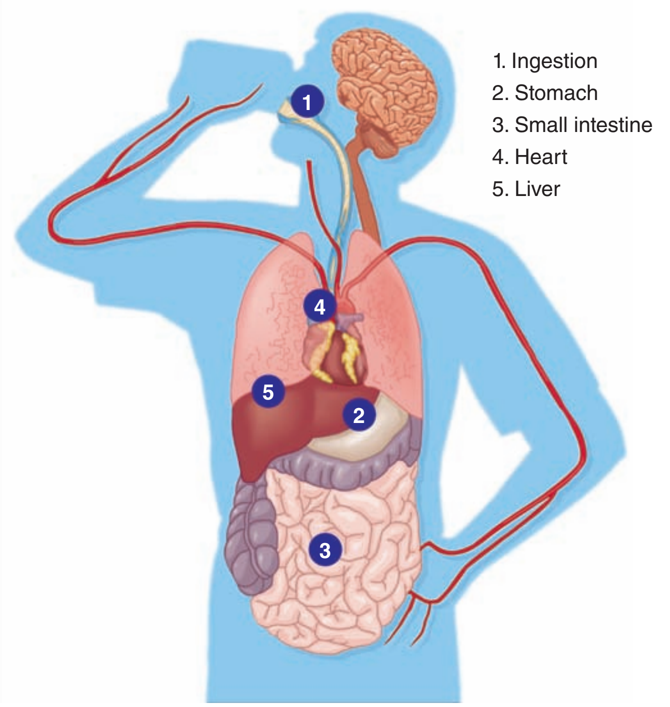
creative about fermenting alcohol from just about any fruit or vegetable, partly because many foods contain sugar. Alcoholic drinks have included mead from honey, sake from rice, wine from palm, mescal and pulque from agave and cactus, liquor from maple syrup, liquor from South American jungle fruits, wine from grapes, and beer from grains (Lazare, 1989).

### *Clinical Description*

Although alcohol is a depressant, its initial effect is an apparent stimulation. We generally experience a feeling of well-being, our inhibitions are reduced, and we become more outgoing. This is because what are initially depressed—or slowed—are the inhibitory centers in the brain. With continued drinking, however, alcohol depresses more areas of the brain, which impedes the ability to function properly. Motor coordination is impaired (staggering, slurred speech), reaction time is slowed, we become confused, our ability to make judgments is reduced, and even vision and hearing can be negatively affected, all of which help explain why driving while intoxicated is clearly dangerous.

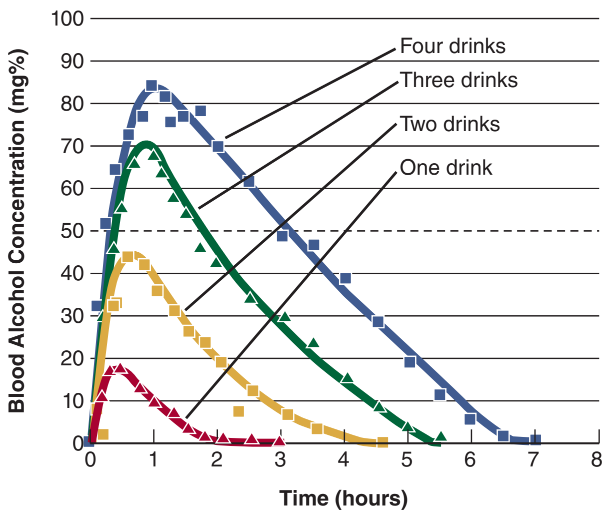
### *Effects*

Alcohol affects many parts of the body (see ■ Figure 11.2). After it is ingested, it passes through the esophagus (1 in Figure 11.2) and into the stomach (2), where small amounts are absorbed. From there, most of it travels to the small intestine (3), where it is easily absorbed into the bloodstream. The circulatory system distributes the alcohol throughout the body, where it contacts every major organ, including the heart (4). Some of the alcohol goes to the lungs, where it vaporizes and is exhaled, a phenomenon that is the basis for the *breathalyzer test* that measures levels of intoxication. As alcohol passes through the liver (5), it is broken down or metabolized into carbon dioxide and water by enzymes (Maher, 1997). ■ Figure 11.3 shows how much time it takes to metabolize one to four drinks, with the dotted line showing when driving becomes impaired (National Institute on Alcohol Abuse and Alcoholism, 1997).



■ **FIGURE 11.2** The path traveled by alcohol throughout the body (see text for complete description).

Most substances we describe in this chapter, including marijuana, opiates, and tranquilizers, interact with specific receptors in the brain cells. The effects of alcohol, however, are more complex. Alcohol influences a number of neuroreceptor systems, which makes it difficult to study. For example, the *gamma-aminobutyric acid (GABA)* system, which we discussed in



■ **FIGURE 11.3** Blood alcohol concentration after the rapid consumption of different amounts of alcohol by eight adult, fasting, male subjects. 100 mg% is the legal level of intoxication in most states. 50 mg% is the level at which deterioration of driving skills begins. Chapters 2 and 5, seems to be particularly sensitive to alcohol. GABA, as you will recall, is an inhibitory neurotransmitter. Its major role is to interfere with the firing of the neuron it attaches to. When GABA attaches to its receptor, chloride ions enter the cell and make it less sensitive to the effects of other neurotransmitters. Alcohol seems to reinforce the movement of these chloride ions; as a result, the neurons have difficulty firing. In other words, although alcohol seems to loosen our tongues and makes us more sociable, it makes it difficult for neurons to communicate with one another (Strain, 2009). Because the GABA system seems to act on our feelings of anxiety, alcohol's anti-anxiety properties may result from its interaction with the GABA system.

The *glutamate system* is under study for its role in the effects of alcohol. In contrast to the GABA system, the glutamate system is excitatory, helping neurons fire. It is suspected to involve learning and memory, and it may be the avenue through which alcohol affects our cognitive abilities. Blackouts, the loss of memory for what happens during intoxication, may result from the interaction of alcohol with the glutamate system. The serotonin system also appears to be sensitive to alcohol. This neurotransmitter system affects mood, sleep, and eating behavior and is thought to be responsible for alcohol cravings (Strain, 2009). Because alcohol affects so many neurotransmitter systems, we should not be surprised that it has such widespread and complex effects.

## Substance Use Disorder: Tim

*"When I drink, I don't care about anything, as long as I'm drinking. Nothing bothers me. The world doesn't bother me. So when I'm not drinking, the problems come back, so you drink again. The problems will always be there. You just don't realize it when you're drinking. That's why people tend to drink a lot."*

Abnormal Psychology Inside Out. Produced by Ira Wohl, Only Child Motion Pictures

The long-term effects of heavy drinking are often severe. Withdrawal from chronic alcohol use typically includes hand tremors and, within several hours, nausea or vomiting, anxiety, transient hallucinations, agitation, insomnia, and, at its most extreme, **withdrawal delirium** (or **delirium tremens—**the **DTs**), a condition that can produce frightening hallucinations and body tremors. The devastating experience of delirium tremens can be reduced with adequate medical treatment (Schuckit, 2009b).

Whether alcohol will cause organic damage depends on genetic vulnerability, the frequency of use, the length of drinking binges, the blood alcohol levels attained during the drinking periods, and whether the body is given time to recover between binges. Consequences of long-term excessive drinking include liver disease, pancreatitis, cardiovascular disorders, and brain damage.

Part of the folklore concerning alcohol is that it permanently kills brain cells (neurons). As you will see later, this may not be true. Some evidence for brain damage comes from the experiences of people who are alcohol dependent and experience blackouts, seizures, and hallucinations. Memory and the ability to perform certain tasks may also be impaired. More seriously, two types of organic brain syndromes may result from long-term heavy alcohol use: dementia and Wernicke-Korsakoff syndrome. *Dementia,* which we discuss more fully in Chapter 15, involves the general loss of intellectual abilities and can be a direct result of neurotoxicity or "poisoning of the brain" by excessive amounts of alcohol (Leamon et al., 2008). *Wernicke-Korsakoff syndrome* results in confusion, loss of muscle coordination, and unintelligible speech (Schuckit, 2009b); it is believed to be caused by a deficiency of thiamine, a vitamin metabolized poorly by heavy drinkers. The dementia caused by this disease does not go away once the brain is damaged.

The effects of alcohol abuse extend beyond the health and well-being of the drinker. **Fetal alcohol syndrome (FAS)**

is now generally recognized as a combination of problems that can occur in a child whose mother drank while she was pregnant. These problems include fetal growth retardation, cognitive deficits, behavior problems, and learning difficulties (Gray, Mukherjee, & Rutter, 2009). In addition, children with FAS often have characteristic facial features.

It is interesting that not all women who drink during pregnancy are at equal risk for having children with FAS. African Americans and the Apache and some Indian tribes of the American Southwest appear to be at greater risk for having children with FAS (Wall, Carr, & Ehlers, 2003) than Caucasian women. We metabolize alcohol with the help of an enzyme called **alcohol dehydrogenase (ADH)** (Schuckit, 2009b). Three different forms of this enzyme have been identified (beta-1, beta-2, and beta-3 ADH); one form (beta-3 ADH) is found most often in African Americans. Initial work also shows that beta-3 ADH may be prevalent among children with FAS. What these two findings suggest is that, in addition to the drinking habits of the mother, the likelihood a child will have FAS may depend on whether there is a genetic tendency to have certain enzymes. Children from certain racial groups may thus be more susceptible to FAS than are others. If this research is confirmed, we may have a way of identifying parents who might put their unborn children at increased risk for FAS.

©David H. Wells/Terra/Corbis

▲ Physical characteristics of fetal alcohol syndrome (FAS) include skin folds at the corners of the eyes, low nasal bridge, short nose, groove between nose and upper lip, small head circumference, small eye opening, small midface, and thin upper lip.

### *Statistics on Use and Abuse*

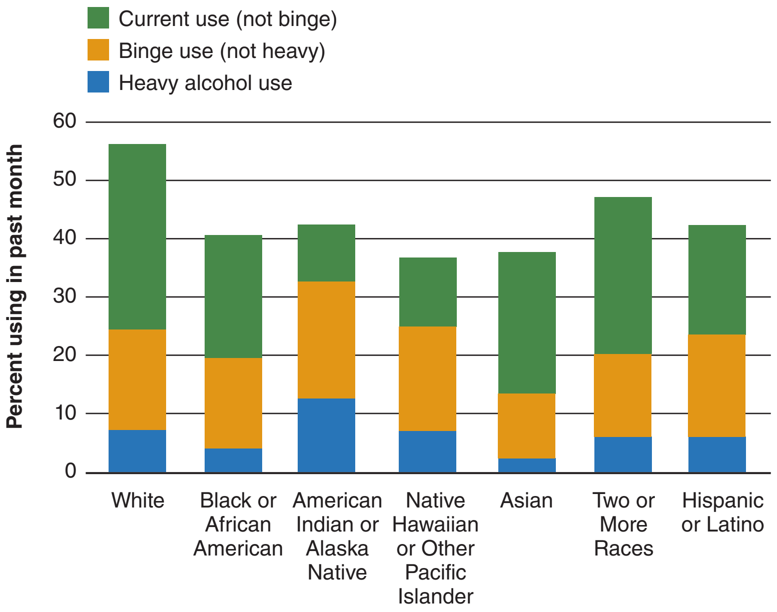
Because alcohol consumption is legal in the United States, we know more about it than about most other psychoactive substances we discuss in this chapter (with the possible exception of nicotine and caffeine, also legal here). Despite a national history of heavy alcohol use, most adults in the United States characterize themselves as light drinkers or abstainers. On the other hand, about half of all Americans over the age of 12 report being current drinkers of alcohol, and there are considerable differences among people from different racial and ethnic backgrounds (see ■ Figure 11.4; Substance Abuse and Mental Health Services Administration, 2009). Whites report the highest frequency of drinking (56.5%); drinking is lowest among Native Hawaiians (37.3%).

About 58 million Americans (23%) report binge drinking (five or more drinks on the same occasion) in the past month—an alarming statistic (Substance Abuse and Mental Health Services Administration, 2009). Again, there are racial differences, with Asians reporting the lowest level of binge drinking (11.9%) and American Indians (24.4%) and Hispanics (25.6%) reporting the highest. In a large survey among college-age men and women, about 42% of respondents said they had gone on a binge of heavy drinking once in the preceding 2 weeks (Presley & Meilman, 1992). Men, however, were more likely to report several binges in the 2-week period. The same survey found that students with a grade point average of A had no more than 3 drinks per week, whereas D and F students averaged 11 alcoholic drinks per week (Presley & Meilman, 1992). Overall, these data point to the popularity and pervasiveness of drinking in our society.

### *Statistics on Dependence*

Our everyday experience tells us that not everyone who drinks becomes dependent on alcohol or abuses it. However, researchers estimate that more than 3 million adults are alcohol dependent (Substance Abuse and Mental Health Services Administration, 2009).

Outside the United States, rates of alcohol abuse and dependence vary widely. The prevalence of alcohol dependence in Peru is about 35%; in South Korea, it is approximately 22%; it is about



■ **FIGURE 11.4** Alcohol use across racial groups. Binge drinking is defined as drinking five or more drinks on one occasion at least once per month, and heavy alcohol use is defined as binge drinking for five or more days in a month. (From Substance Abuse and Mental Health Services Administration, Office of Applied Studies. (2006). *Results from the 2005 National Survey on Drug Use and Health: National Findings,* NSDUH Series H-30, DHHS Publication No. SMA 06-4194. Rockville, MD: Author.)

3.5% in Taipei and as low as 0.45% in Shanghai (Helzer & Canino, 1992; Yamamoto, Silva, Sasao, Wang, & Nguyen, 1993). Such cultural differences can be accounted for by different attitudes toward drinking, the availability of alcohol, physiological reactions, and family norms and patterns.

### Progression

Remember that Danny went through periods of heavy alcohol and drug use but also had times when he was relatively "straight" and did not use drugs. Similarly, many people who abuse alcohol or are dependent on it fluctuate between drinking heavily, drinking "socially" without negative effects, and being abstinent (not drinking) (Schuckit, 2009a). It seems that about 20% of people with severe alcohol dependence have a spontaneous remission (they are able to stop drinking on their own) and do not reexperience problems with drinking.

It used to be thought that once problems arose with drinking they would become steadily worse, following a predictable downward pattern as long as the person kept drinking (Sobell & Sobell, 1993). In other words, like a disease that isn't treated properly, alcoholism will get progressively worse if left unchecked. First championed by Jellinek more than 50 years ago, this view continues to influence the way people view and treat the disorder (Jellinek, 1946, 1952, 1960). Unfortunately, Jellinek based his model of the progression of alcohol use on a now famous but faulty study (Jellinek, 1946), which we briefly review.

In 1945, the newly formed self-help organization Alcoholics Anonymous (AA) sent out some 1,600 surveys to its members asking them to describe symptoms related to drinking, such as feelings of guilt or remorse and rationalizations about their actions, and to note when these reactions first occurred. Only 98 of the almost 1,600 surveys were returned, however. As you know, such a small response could seriously affect data interpretation. A group of 98 may be different from the group as a whole, so they may not represent the typical person with alcohol problems. Also, because the responses were retrospective (participants were recalling past events), their reports may be inaccurate. Despite these and other problems, Jellinek agreed to analyze the data, and he developed a four-stage model for the progression of alcoholism based on this limited information (Jellinek, 1952). According to his model, individuals go through a *prealcoholic stage* (drinking occasionally with few serious consequences), a *prodromal stage* (drinking heavily but with few outward signs of a problem), a *crucial stage* (loss of control, with occasional binges), and a *chronic stage* (the primary daily activities involve getting and drinking alcohol). Attempts by other researchers to confirm this progression of stages have not been successful (Schuckit, Smith, Anthenelli, & Irwin, 1993).

It appears instead that the course of alcohol dependence may be progressive for most people, whereas the course of alcohol abuse may be more variable. For example, early use of alcohol may predict later abuse. A study of almost 6,000 lifetime drinkers found that drinking at an early age—from ages 11 to 14—was predictive of later alcohol use disorders (DeWitt, Adlaf, Offord, & Ogborne, 2000). A second study followed 636 male inpatients in an alcohol rehabilitation center (Schuckit et al., 1993). Among these chronically alcohol-dependent men, a general progression of alcohol-related life problems did emerge, although not in the specific pattern proposed by Jellinek. Three quarters of the men reported moderate consequences of their drinking, such as demotions at work, in their 20s. During their 30s, the men had more serious problems, such as regular blackouts and signs of alcohol withdrawal. By their late 30s and early 40s, these men demonstrated long-term serious consequences of their drinking, which included hallucinations, withdrawal convulsions, and hepatitis or pancreatitis. This study suggests a common pattern among people with chronic alcohol abuse and dependence, one with increasingly severe consequences. This progressive pattern is not inevitable for everyone who abuses alcohol, although we do not as yet understand what distinguishes those who are and those who are not susceptible (Schuckit, 2009a).

Finally, statistics often link alcohol with violent behavior (Bye, 2007). Numerous studies have found that many people who commit such violent acts as murder, rape, and assault are intoxicated at the

©Robin Nelson/PhotoEdit

▲ Intoxication is often involved in cases of domestic violence.

time of the crime (Murdoch, Pihl, & Ross, 1990). We hope you are skeptical of this type of correlation. Just because drunkenness and violence overlap does not mean that alcohol will necessarily make you violent. Laboratory studies show that alcohol does make participants more aggressive (Bushman, 1993). However, whether a person behaves aggressively outside the laboratory probably involves a number of interrelated factors, such as the quantity and timing of alcohol consumed, the person's history of violence, expectations about drinking, and what happens to the individual while intoxicated. Alcohol does not *cause* aggression, but it may increase a person's likelihood of engaging in impulsive acts and it may impair the ability to consider the consequences of acting impulsively (Bye, 2007). Given the right circumstances, such impaired rational thinking may increase a person's risk of behaving aggressively.

## Sedative, Hypnotic, or Anxiolytic Substance Use Disorders

The general group of depressants also includes sedative (calming), hypnotic (sleep-inducing), and anxiolytic (anxiety-reducing) drugs (Ciraulo & Sarid-Segal, 2009). These drugs include barbiturates and benzodiazepines. **Barbiturates** (which include Amytal, Seconal, and Nembutal) are a family of sedative drugs first synthesized in Germany in 1882 (Cozanitis, 2004). They were prescribed to help people sleep and replaced such drugs as alcohol and opium. Barbiturates were widely prescribed by physicians during the 1930s and 1940s, before their addictive properties were fully understood. By the 1950s, they were among the drugs most abused by adults in the United States (Franklin & Frances, 1999).

**Benzodiazepines** (which today include Valium, Xanax, Rohypnol, and Halcion) have been used since the 1960s, primarily to reduce anxiety. These drugs were originally touted as a miracle cure for the anxieties of living in our highly pressured technological society. Although in 1980 the U.S. Food and Drug Administration ruled that they are not appropriate for reducing the tension and anxiety resulting from everyday stresses and strains, an estimated 74 million prescriptions are written for benzodiazepines in the United States each year (Ciraulo & Sarid-Segal, 2009). In general, benzodiazepines are considered much safer than barbiturates, with less risk of abuse and dependence. Reports on the misuse of Rohypnol, however, show how dangerous even these benzodiazepine drugs can be. Rohypnol (otherwise known as "forget-me-pill," "roofenol," "roofies," "ruffies") gained a following among teenagers in the 1990s because it has the same effect as alcohol without the telltale odor. However, there have been numerous incidents of men giving the drug to women without their knowledge, making it easier for them to engage in date rape (Nicoletti, 2009).

### Clinical Description

At low doses, barbiturates relax the muscles and can produce a mild feeling of well-being. However, larger doses can have results similar to those of heavy drinking: slurred speech and problems walking, concentrating, and working. At extremely high doses, the diaphragm muscles can relax so much that they cause death by suffocation. Overdosing on barbiturates is a common means of suicide.

Like the barbiturates, benzodiazepines are used to calm an individual and induce sleep. In addition, drugs in this class are prescribed as muscle relaxants and anticonvulsants (antiseizure medications) (Ciraulo & Sarid-Segal, 2009). People who use them for nonmedical reasons report first feeling a pleasant high and a reduction of inhibition, similar to the effects of drinking alcohol. However, with continued use, tolerance and dependence can develop. Users who try to stop taking the drug experience symptoms like those of alcohol withdrawal (anxiety, insomnia, tremors, and delirium).

The *DSM-IV-TR* criteria for sedative, hypnotic, and anxiolytic drug use disorders do not differ substantially from those for alcohol disorders. Both include maladaptive behavioral changes such as inappropriate sexual or aggressive behavior, variable moods, impaired judgment, impaired social or occupational functioning, slurred speech, motor coordination problems, and unsteady gait.

Like alcohol, sedative, hypnotic, and anxiolytic drugs affect the brain by influencing the GABA neurotransmitter system (Ciraulo & Sarid-Segal, 2009), although by slightly different mechanisms; as a result, when people use alcohol with any of these drugs or combine multiple types there can be synergistic effects. In other words, if you drink alcohol after taking a benzodiazepine or barbiturate or combine these drugs, the total effects can reach dangerous levels. One theory about actress Marilyn Monroe's death in 1962 is that she combined alcohol with too many barbiturates and unintentionally killed herself. Actor Heath Ledger's death in 2008 was attributed to the combined effects of oxycodone and a variety of other barbiturates and benzodiazepines.

### Statistics

Barbiturate use has declined and benzodiazepine use has increased since 1960 (Substance Abuse and Mental Health Services Administration, 2009). Of those seeking treatment for substance-related problems, less than 1% present problems with benzodiaz-

**DSM-IV-TR**

**Table 11.5** Diagnostic Criteria for Sedative, Hypnotic, or Anxiolytic Intoxication

**A.** Recent use of a sedative, hypnotic, or anxiolytic drug.

**B.** Clinically significant maladaptive behavioral or psychological changes (e.g., inappropriate sexual or aggressive behavior, mood lability, impaired judgment, impaired social or occupational functioning) that developed during, or shortly after, sedative, hypnotic, or anxiolytic use.

**C.** One or more of the following signs, developing during, or shortly after, sedative, hypnotic, or anxiolytic use:

1. Slurred speech
2. Incoordination
3. Unsteady gait
4. Nystagmus
5. Impairment in attention or memory
6. Stupor or coma

epines compared to other drugs of abuse. Those who do seek help with these drugs tend to be female, Caucasian, and over the age of 35 (Substance Abuse and Mental Health Services Administration, 2009).

## Concept Check 11.1

### Part A

Check your understanding of substance-related definitions by stating whether the following case summaries describe (a) use, (b) intoxication, (c) abuse, or (d) dependence.

1. Giya started a new job 5 weeks ago and is about to be fired. This is her third job for the year. She has been absent from work at least once a week for the past 5 weeks. She was reprimanded in the past after being seen at a local pub in a drunken state during regular office hours although she called in sick. At her previous job, she was fired after she came to work unable to conduct herself appropriately and with alcohol on her breath. When confronted about her problems, Giya went to the nearest bar and drank some more to forget the situation. ______________
2. Brennan scored the winning goal for his high school soccer team and his friends take him out to celebrate. He doesn't smoke, but he doesn't mind drinking alcohol occasionally. Because Brennan had such a good game, he decides to have a few drinks. Despite his great performance in the game, he is easily irritated, laughing one minute and yelling the next. The more Brennan rambles on about his game-winning goal, the more difficult it is to understand him. ______________
3. Marti is a 24-year-old college student who started drinking heavily when he was 15. Marti drinks a moderate amount every night, unlike his schoolmates who get drunk at weekend parties. In high school, he would become drunk after about four beers; now his tolerance has more than doubled. Marti claims alcohol relieves the pressures of college life. He once attempted to quit drinking, but he had chills, fever, diarrhea, nausea and vomiting, and body aches and pains. ______________
4. Over the past year Henry picked up a habit of having a cigarette every day after lunch. Instead of sitting in the lounge with his friends he goes to his favorite spot in the courtyard and has his cigarette. If for some reason he is unable to have his cigarette after lunch, he is not dependent on it and can still function normally.
   __________________

### Part B

Match the following disorders with their corresponding effects: (a) substance-related disorder, (b) dementia, (c) impulse-control disorder, (d) alcohol use disorder, and (e) Wernicke-Korsakoff syndrome.

5. Disorder that deprives a person of the ability to resist acting on a drive or temptation. ______________
6. Disorder in which the effects of the drug impede the ability to function properly by affecting vision, motor control, reaction time, memory, and hearing.
   _______________________
7. The decline of intellectual abilities through, for example, excess consumption of alcohol. ________________
8. A class of disorders that affects the way people think, feel, and behave. ______________

# Stimulants

Of all the psychoactive drugs used in the United States, the most commonly consumed are stimulants. Included in this group are caffeine (in coffee, chocolate, and many soft drinks), nicotine (in tobacco products such as cigarettes), amphetamines, and cocaine. You probably used caffeine when you got up this morning. In contrast to the depressant drugs, stimulants—as their name suggests—make you more alert and energetic. They have a long history of use. Chinese physicians, for example, prescribed an amphetamine compound called ma-huang *(Ephedra sinica)* for more than 5,000 years for illnesses such as headaches, asthma, and the common cold (Fushimi, Wang, Ebisui, Cai, & Mikage, 2008). We describe several stimulants and their effects on behavior, mood, and cognition.

## Amphetamine Use Disorders

At low doses, amphetamines can induce feelings of elation and vigor and can reduce fatigue. You literally feel "up." However, after a period of elevation, you come back down and "crash," feeling depressed or tired. In sufficient quantities, stimulants can lead to **amphetamine use disorders**.

Amphetamines are manufactured in the laboratory; they were first synthesized in 1887 and later used as a treatment for asthma and as a nasal decongestant (McCann & Ricaurte, 2009). Because amphetamines also reduce appetite, some people take them to lose weight. Adolph Hitler, partly because of his other physical maladies, became addicted to amphetamines (Judge & Rusyniak, 2009). Long-haul truck drivers, pilots, and some college students trying to "pull all-nighters" use amphetamines to get that extra energy boost and stay awake. Amphetamines are prescribed for people with *narcolepsy,* a sleep disorder characterized by excessive sleepiness (discussed in Chapter 8). Some of these drugs (Ritalin) are even given to children with *attention-deficit/hyperactivity disorder (ADHD)* (discussed in Chapter 14), although these too are being abused for their psychostimulant effects. One study found that as many as 1 in 10 students at one college reported using prescription stimulants illegally (Carroll, McLaughlin, & Blake, 2006).

*DSM-IV-TR* diagnostic criteria for amphetamine intoxication include significant behavioral symptoms, such as euphoria or affective blunting (a lack of emotional expression), changes in sociability, interpersonal sensitivity, anxiety, tension, anger, stereo-

**DSM-IV-TR**

**Table 11.6** Diagnostic Criteria for Amphetamine (or Related Substance) Intoxication

**A.** Use of amphetamine or a related substance (e.g., methylphenidate).

**B.** Clinically significant maladaptive behavioral or psychological changes (e.g., euphoria or affective blunting; changes in sociability; hypervigilance; interpersonal sensitivity, anxiety, tension, or anger; stereotyped behaviors; impaired judgment or impaired social or occupational functioning) that developed during, or shortly after, use of amphetamine or a related substance.

**C.** Two (or more) of the following, developing during, or shortly after, use of amphetamine or a related substance:

1. Tachycardia or bradycardia
2. Pupillary dilation
3. Elevated or lowered blood pressure
4. Perspiration or chills
5. Nausea or vomiting
6. Evidence of weight loss
7. Psychomotor agitation or retardation
8. Muscular weakness, respiratory depression, chest pain, or cardiac arrhythmias
9. Confusion, seizures, dyskinesias, dystonias, or coma

**D.** The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder.

typed behaviors, impaired judgment, and impaired social or occupational functioning. In addition, physiological symptoms occur during or shortly after amphetamine or related substances are ingested and can include heart rate or blood pressure changes, perspiration or chills, nausea or vomiting, weight loss, muscular weakness, respiratory depression, chest pain, seizures, or coma. Severe intoxication or overdose can cause hallucinations, panic, agitation, and paranoid delusions (Leamon et al., 2008). Amphetamine tolerance builds quickly, making it doubly dangerous. Withdrawal often results in apathy, prolonged periods of sleep, irritability, and depression.

Periodically, certain "designer drugs" appear in local miniepidemics. An amphetamine called methylene-dioxymethamphetamine (MDMA), first synthesized in 1912 in Germany, was used as an appetite suppressant (McCann & Ricaurte, 2009). Recreational use of this drug, now commonly called Ecstasy, rose sharply in the late 1980s. After methamphetamine, MDMA is the club drug most often bringing people to emergency rooms, and it has passed LSD in frequency of use (Substance Abuse and Mental Health Services Administration, 2009). Its effects are described by users in a variety of ways: Ecstasy makes you "feel happy" and "love everyone and everything"; "music feels better" and "it's more fun to dance"; "You can say what is on your mind without worrying what others will think" (Levy, O'Grady, Wish, & Arria, 2005, p. 1431). A purified, crystallized form of amphetamine, called methamphetamine (commonly referred to as "crystal meth" or "ice"), is ingested through smoking. This drug causes marked aggressive tendencies and stays in the system longer than cocaine, making it particularly dangerous. This drug gained popularity in the gay community, although its use has now spread to others (Parsons, Kelly, & Weiser, 2007). However enjoyable these various amphetamines may be in the short term, the potential for users to become dependent on them is extremely high, with great risk for long-term difficulties.

Amphetamines stimulate the central nervous system by enhancing the activity of norepinephrine and dopamine. Specifically, amphetamines help the release of these neurotransmitters and block their reuptake, thereby making more of them available throughout the system (McCann & Ricaurte, 2009). Too much amphetamine—and therefore too much dopamine and norepinephrine—can lead to hallucinations and delusions. As we see in Chapter 13, this effect has stimulated theories on the causes of schizophrenia, which can also include hallucinations and delusions.

## Cocaine Use Disorders

The use and misuse of drugs, such as those leading to **cocaine use disorders**, wax and wane according to societal fashion, moods, and sanctions. Cocaine replaced amphetamines as the stimulant of choice in the 1970s (Jaffe, Rawson, & Ling, 2005). Cocaine is derived from the leaves of the coca plant, a flowering bush indigenous to South America. In his essay "On Coca" (1885/1974, p. 60), a young Sigmund Freud wrote of cocaine's magical properties: "I have tested [the] effect of coca, which wards off hunger, sleep, and fatigue and steels one to intellectual effort, some dozen times on myself."

Latin Americans have chewed coca leaves for centuries to get relief from hunger and fatigue (Gootenberg, 2009). Cocaine was introduced into the United States in the late 19th century; it was widely used from then until the 1920s. In 1885, Parke, Davis & Co. manufactured coca and cocaine in 15 forms, including coca-leaf cigarettes and cigars, inhalants, and crystals. For people who couldn't afford these products, a cheaper way to get cocaine was in Coca-Cola, which up until 1903 contained a small amount (60 mg of cocaine per 8-ounce serving) (Weiss & Iannucci, 2009).

### Clinical Description

Like the amphetamines, in small amounts cocaine increases alertness, produces euphoria, increases blood pressure and pulse, and causes insomnia and loss of appetite. Remember that Danny snorted (inhaled) cocaine when he partied through the night with his friends. He later said the drug made him feel powerful and invincible—the only way he really felt self-confident. The

### DSM-IV-TR **Table 11.7** Diagnostic Criteria for Cocaine Intoxication

**A.** Recent use of cocaine.

**B.** Clinically significant maladaptive behavioral or psychological changes (e.g., euphoria or affective blunting; changes in sociability; hypervigilance; interpersonal sensitivity; anxiety, tension, or anger; stereotyped behaviors; impaired judgment or impaired social or occupational functioning) that developed, during or shortly after, use of cocaine.

**C.** Two (or more) of the following, developing during, or shortly after, cocaine use:

1. Tachycardia or bradycardia
2. Pupillary dilation
3. Elevated or lowered blood pressure
4. Perspiration or chills
5. Nausea or vomiting
6. Evidence of weight loss
7. Psychomotor agitation or retardation
8. Muscular weakness, respiratory depression, chest pain, or cardiac arrhythmias
9. Confusion, seizures, dyskinesias, dystonias, or coma

**D.** The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder.

Specify if:

With perceptual disturbances

*Source:* Reprinted with permission, from American Psychiatric Association. (2000). *Diagnostic and statistical manual of mental disorders* (4th ed., text revision). Washington, DC: Author, © 2000 American Psychiatric Association.

effects of cocaine are short lived; for Danny they lasted less than an hour, and he had to snort repeatedly to keep himself up. During these binges, he often became paranoid, experiencing exaggerated fears that he would be caught or that someone would steal his cocaine. Such paranoia—referred to as *cocaine-induced paranoia*—is common among cocaine abusers, occurring in two thirds or more (Kalayasiri et al., 2006). Cocaine also makes the heart beat more rapidly and irregularly, and it can have fatal consequences, depending on a person's physical condition and the amount of the drug ingested. Billy Mays, the TV salesman for products such as Oxi-Clean, died of heart disease in 2009 with cocaine listed as a contributory cause of death.

We saw that alcohol can damage the developing fetus. It has also been suspected that the use of cocaine (especially crack) by pregnant women may adversely affect their babies. Crack babies appear at birth to be more irritable than normal babies and have long bouts of high-pitched crying. They were originally thought to have permanent brain damage, although recent research suggests that the effects are less dramatic than first feared (Schiller & Allen, 2005). Some work suggests that many children born to mothers who have used cocaine during pregnancy may have decreased birth weight and decreased head circumference, and are at increased risk for later behavior problems (Richardson, Goldschmidt, & Willford, 2009). Complicating the evaluation of children born to mothers who use cocaine is that their mothers almost always used other substances as well, including alcohol and nicotine. Many of these children are raised in disrupted home environments, which further complicates the picture. Continuing research should help us better understand the negative effects of cocaine on children. One study suggests that prenatal cocaine exposure may affect the fetus's "biological clock"—the suprachiasmatic nucleus (Weaver, Rivkees, & Reppert, 1992), which would cause a reaction similar to jet lag that might contribute to the irritability and other problems experienced by the newborn.

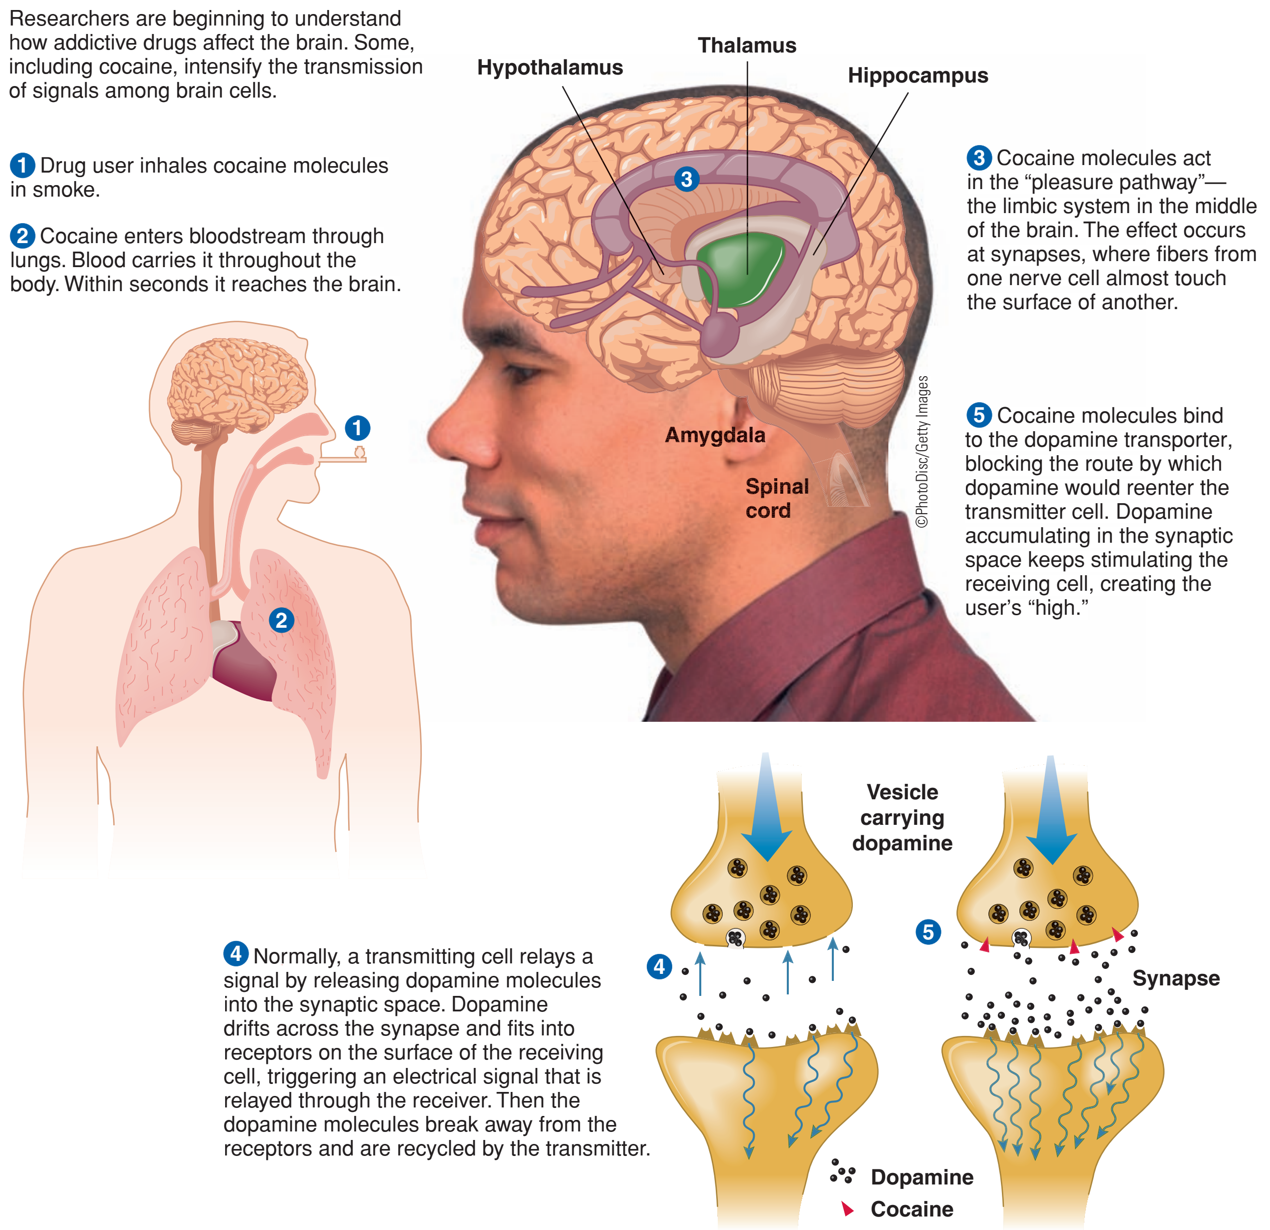
### Statistics

In the United States, more than 1.9 million people report using cocaine each year, more than any other drug besides marijuana (Substance Abuse and Mental Health Services Administration, 2009). White males account for about a third of all admissions to emergency rooms for cocaine-related problems (29%) followed by black males (23%), white females (18%), and black females (12%) (Substance Abuse and Mental Health Services Administration, 2002). Approximately 17% of cocaine users have also used crack cocaine (a crystallized form of cocaine that is smoked) (Closser, 1992). One estimate is that about 0.2% of Americans have tried crack and that an increasing proportion of the abusers seeking treatment are young, unemployed adults living in urban areas (Substance Abuse and Mental Health Services Administration, 2009).

Cocaine is in the same group of stimulants as amphetamines because it has similar effects on the brain. The "up" seems to come primarily from the effect of cocaine on the dopamine system. Look at ■ Figure 11.5 to see how this action occurs. Cocaine enters the bloodstream and is carried to the brain. There the cocaine molecules block the reuptake of dopamine. As you know, neurotransmitters released at the synapse stimulate the next neuron and then are recycled back to the original neuron. Cocaine seems to bind to places where dopamine neurotransmitters reenter their home neuron, blocking their reuptake. The dopamine that cannot be taken in by the neuron remains in the synapse, causing repeated stimulation of the next neuron. This stimulation of the dopamine neurons in the "pleasure pathway" (the site in the brain that seems to be involved in the experience of pleasure) causes the high associated with cocaine use.

As late as the 1980s, many felt cocaine was a wonder drug that produced feelings of euphoria without being addictive (Weiss & Iannucci, 2009). Such a conservative source as the *Comprehensive Textbook of Psychiatry* in 1980 indicated that "taken no more than two or three times per week, cocaine creates no serious problems" (Grinspoon & Bakalar, 1980). Just imagine—a drug that gives you extra energy, helps you think clearly and more creatively, and lets you accomplish more throughout the day, all without any negative side effects! In our highly competitive and complex technological society, this would be a dream come true. But, as you probably realize, such temporary benefits have a high cost. Cocaine fooled us. Dependence does not resemble that of many other drugs early on; typically, people find only that they have a growing inability to resist taking more (Weiss & Iannucci, 2009). Few negative effects are noted at first; however, with continued use, sleep is disrupted, increased tolerance causes a need for higher doses, paranoia and other negative symptoms set in, and the cocaine user gradually becomes socially isolated.

Again, Danny's case illustrates this pattern. He was a social user for a number of years, using cocaine only with friends and only occasionally. Eventually, he had more frequent episodes of



Researchers are beginning to understand how addictive drugs affect the brain. Some, including cocaine, intensify the transmission of signals among brain cells.

① Drug user inhales cocaine molecules in smoke.

② Cocaine enters bloodstream through lungs. Blood carries it throughout the body. Within seconds it reaches the brain.

③ Cocaine molecules act in the "pleasure pathway"—the limbic system in the middle of the brain. The effect occurs at synapses, where fibers from one nerve cell almost touch the surface of another.

④ Normally, a transmitting cell relays a signal by releasing dopamine molecules into the synaptic space. Dopamine drifts across the synapse and fits into receptors on the surface of the receiving cell, triggering an electrical signal that is relayed through the receiver. Then the dopamine molecules break away from the receptors and are recycled by the transmitter.

⑤ Cocaine molecules bind to the dopamine transporter, blocking the route by which dopamine would reenter the transmitter cell. Dopamine accumulating in the synaptic space keeps stimulating the receiving cell, creating the user's "high."

excessive use or binges, and he found himself increasingly craving the drug between binges. After the binges, Danny would crash and sleep. Cocaine withdrawal isn't like that of alcohol. Instead of rapid heartbeat, tremors, or nausea, withdrawal from cocaine produces pronounced feelings of apathy and boredom. Think for a minute how dangerous this type of withdrawal is. First, you're bored with everything and find little pleasure from the everyday activities of work or relationships. The one that can "bring you back to life" is cocaine. As you can imagine, a particularly vicious cycle develops: Cocaine is abused, withdrawal causes apathy, cocaine abuse resumes. The atypical withdrawal pattern misled people into believing that cocaine was not addictive. We now know that cocaine abusers go through patterns of tolerance and withdrawal comparable to those experienced by abusers of other psychoactive drugs (Weiss & Iannucci, 2009).

## Nicotine Use Disorders

When you think of addicts, what image comes to mind? Do you see dirty and disheveled people huddled on an old mattress in an abandoned building, waiting for the next fix? Do you picture businesspeople huddled outside a city building on a rainy afternoon furtively smoking cigarettes? Both these images are accurate, because the nicotine in tobacco is a psychoactive substance that produces patterns of dependence, tolerance, and withdrawal—**nicotine use disorders**—comparable to those of the other drugs we have discussed so far (Hughes, 2009). In 1942, the Scottish physician Lennox Johnson "shot up" nicotine extract and found after 80 injections that he liked it more than cigarettes and felt deprived without it (Kanigel, 1988). This colorless, oily liquid—called nicotine after Jean Nicot, who introduced tobacco to the

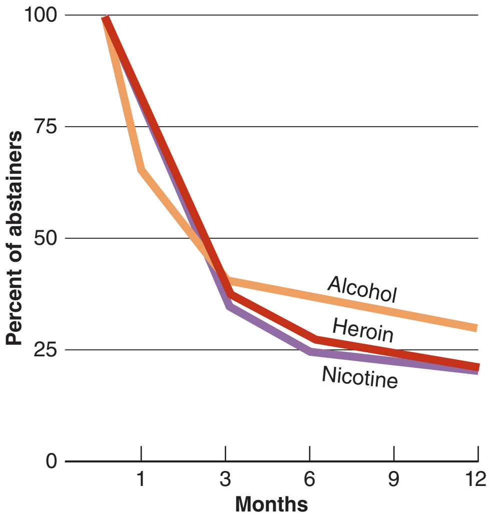
French court in the 16th century—is what gives smoking its pleasurable qualities.

The tobacco plant is indigenous to North America, and Native Americans cultivated and smoked the leaves centuries ago. Today, about 21% of all Americans smoke, which is down from the 42.4% who were smokers in 1965 (Hughes, 2009).

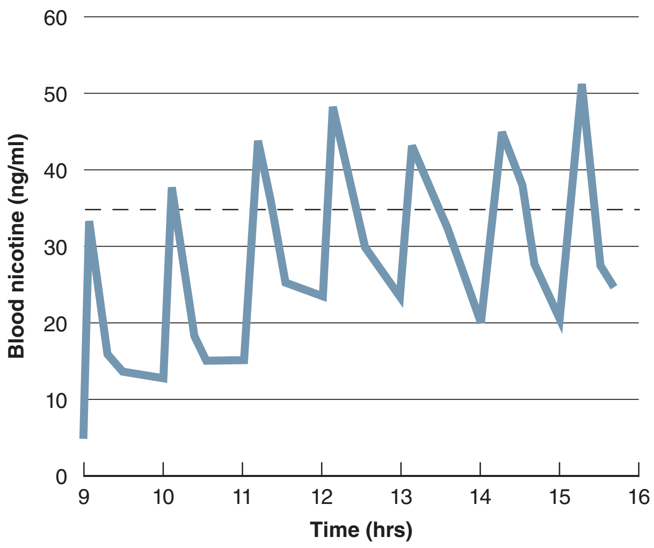
*DSM-IV-TR* does not describe an intoxication pattern for nicotine. Rather, it lists withdrawal symptoms, which include depressed mood, insomnia, irritability, anxiety, difficulty concentrating, restlessness, and increased appetite and weight gain. Nicotine in small doses stimulates the central nervous system; it can relieve stress and improve mood. But it can also cause high blood pressure and increase the risk of heart disease and cancer (Stewart, Cutler, & Rosen, 2009). High doses can blur your vision, cause confusion, lead to convulsions, and sometimes even cause death. Once smokers are dependent on nicotine, going without it causes withdrawal symptoms. If you doubt the addictive power of nicotine, consider that the rate of relapse among people trying to give up drugs is equivalent among those using alcohol, heroin, and cigarettes (see ■ Figure 11.6).

Nicotine is inhaled into the lungs, where it enters the bloodstream. Only 7 to 19 seconds after a person inhales the smoke, the nicotine reaches the brain. Nicotine appears to stimulate specific receptors—nicotinic acetylcholine receptors (nAChRs)—in the midbrain reticular formation and the limbic system, the site of the brain's pleasure pathway (the dopamine system responsible for feelings of euphoria) (Benowitz, 2008). Some evidence also points to how nicotine may affect the fetal brain, possibly increasing the likelihood that children of mothers who smoke during pregnancy will smoke later in life (Kandel, Wu, & Davies, 1994). Smokers dose themselves throughout the day in an effort to keep nicotine at a steady level in the bloodstream (see ■ Figure 11.7; Dalack, Glassman, & Covey, 1993).

Smoking has been linked with signs of negative affect, such as depression, anxiety, and anger (Rasmusson, Anderson, Krishnan-Sarin, Wu, & Paliwal, 2006). For example, many people who quit smoking but later resume report that feelings of depression or anxiety were responsible for the relapse (Hughes, 2009). This finding suggests that nicotine may help improve mood.



■ **FIGURE 11.6** Relapse rates for nicotine compared to alcohol and heroin. Smokers trying to give up cigarettes backslide about as often as alcoholics and heroin addicts. (Adapted, with permission, from Kanigel, R. (1988). October/November. Nicotine becomes addictive. *Science Illustrated,* pp. 12–14, 19–21, © 1988 Science Illustrated.)



■ **FIGURE 11.7** Smoking patterns and nicotine levels. This subject smoked one cigarette an hour, illustrating how smokers inhale more or less deeply or often, to get the desired blood levels of nicotine—on average 35 nanograms per milliliter. (Adapted, with permission, from Kanigel, R. (1988). October/November. Nicotine becomes addictive. *Science Illustrated,* pp. 12–14, 19–21, ©1988 Science Illustrated.)

**DSM-IV-TR** **Table 11.8** Diagnostic Criteria for Nicotine Withdrawal

**A.** Daily use of nicotine for at least several weeks.

**B.** Abrupt cessation of nicotine use, or reduction in the amount of nicotine used, followed within 24 hours by four (or more) of the following signs:

1. Dysphoric or depressed mood
2. Insomnia
3. Irritability, frustration, or anger
4. Anxiety
5. Difficulty concentrating
6. Restlessness
7. Decreased heart rate
8. Increased appetite or weight gain

**C.** The symptoms in criterion B cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

**D.** The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder.

*Source:* Reprinted with permission, from American Psychiatric Association. (2000). *Diagnostic and statistical manual of mental disorders* (4th ed., text revision). Washington, DC: Author, © 2000 American Psychiatric Association.

**DSM-IV-TR** **Table 11.9** Diagnostic Criteria for Caffeine Intoxication

- **A.** Recent consumption of caffeine, usually in excess of 250 mg (e.g., more than 2–3 cups of brewed coffee).
- **B.** Five (or more) of the following signs, developing during, or shortly after, caffeine use:
  1. Restlessness
  2. Nervousness
  3. Excitement
  4. Insomnia
  5. Flushed face
  6. Diuresis
  7. Gastrointestinal disturbance
  8. Muscle twitching
  9. Rambling flow of thought and speech
  10. Tachycardia or cardiac arrhythmia
  11. Periods of inexhaustibility
  12. Psychomotor agitation
- **C.** The symptoms in criterion B cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- **D.** The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder (e.g., anxiety disorder).

*Source:* Reprinted with permission, from American Psychiatric Association. (2000). *Diagnostic and statistical manual of mental disorders* (4th ed., text revision). Washington, DC: Author, © 2000 American Psychiatric Association.

Severe depression is found to occur significantly more often among people with nicotine dependence (Breslau, Kilbey, & Andreski, 1993). Does this mean that smoking causes depression or depression causes smoking? There is a complex and bidirectional relationship between cigarette smoking and negative affect (Leventhal, Kahler, Ray, & Zimmerman, 2009). In other words, being depressed increases your risk of becoming dependent on nicotine, and at the same time, being dependent on nicotine will increase your risk of becoming depressed. Genetic studies suggest that a genetic vulnerability combined with certain life stresses may combine to make you vulnerable to both nicotine dependence and depression (e.g., Kendler et al., 1993). (We discuss evidence for the genetics of smoking when we cover the causes of substance abuse later in this chapter.)

### Caffeine Use Disorders

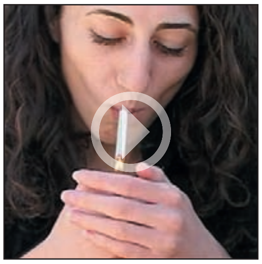
Caffeine is the most common of the psychoactive substances, used regularly by almost 90% of all Americans (Juliano & Griffiths, 2009). Called the "gentle stimulant" because it is thought to be the least harmful of all addictive drugs, caffeine can still lead to **caffeine use disorders**. This drug is found in tea, coffee, many cola drinks sold today, and cocoa products. High levels of caffeine are added to the "energy drinks" that are widely consumed in the United States today but are banned in some European countries (including France, Denmark, and Norway) due to health concerns.

As most of you have experienced firsthand, caffeine in small doses can elevate your mood and decrease fatigue. In larger doses, it can make you feel jittery and can cause insomnia. Because caffeine takes a relatively long time to leave our bodies (about 6 hours), sleep can be disturbed if the caffeine is ingested in the hours close to bedtime. This effect is especially pronounced among those already suffering from insomnia (Saln-Pascual, Castao, Shiromani, Valencia-Flores, & Campos, 2006). As with the other psychoactive drugs, people react variously to caffeine; some are sensitive to it, and others can consume relatively large amounts with little effect. Research suggests that moderate use of caffeine (a cup of coffee per day) by pregnant women does not harm the developing fetus (CARE Study Group, 2008).

As with other stimulants, regular caffeine use can result in tolerance and dependence on the drug. Those of you who have experienced headaches, drowsiness, and a generally unpleasant mood when denied your morning coffee have had the withdrawal symptoms characteristic of this drug (Juliano & Griffiths, 2009). Caffeine's effect on the brain seems to involve the neuromodulator *adenosine* and, to a lesser extent, the neurotransmitter *dopamine* (Herrick, Shecterle, & St. Cyr, 2009). Caffeine seems to block adenosine reuptake. However, we do not yet know the role of adenosine in brain function or whether the interruption of the adenosine system is responsible for the elation and increased energy that come with caffeine use.

## Opioids

The word *opiate* refers to the natural chemicals in the opium poppy that have a narcotic effect (they relieve pain and induce sleep). In some circumstances, they can cause **opioid use disorders**. The broader term *opioids* refers to the family of substances that includes natural opiates, synthetic variations (heroin, methadone, hydrocodone, oxycodone), and the comparable substances that occur naturally in the brain (enkephalins, beta-endorphins, and dynorphins). References to the use of opium as a medicine date back more than 3,500 years (Strain, Lofwall, & Jaffe, 2009). In *The Wizard of Oz,* the Wicked Witch of the West puts Dorothy, Toto, and their companions to sleep by making them walk through a field of poppies, a literary allusion to the opium poppies used to produce morphine, codeine, and heroin.



### Nicotine Dependence

*"You can't simply focus on nicotine itself. Many medications do that—they focus on replacing the nicotine, such as nicotine gum or the patch—and that's valuable, but you really have to focus on all the triggers, the cues, and the environment."*

**Go to Psychology CourseMate at www.cengagebrain.com to watch this video.**

Just as the poppies lull the Tin Man, the Scarecrow, Dorothy, the Cowardly Lion, and Toto, opiates induce euphoria, drowsiness, and slowed breathing. High doses can lead to death if respiration is completely depressed. Opiates are also analgesics, substances that help relieve pain. People are sometimes given morphine before and after surgery to calm them and help block pain.

Withdrawal from opioids can be so unpleasant that people may continue to use these drugs despite a sincere desire to stop. However, barbiturate and alcohol withdrawal can be even more distressing. Even so, people who cease or reduce their opioid intake begin to experience symptoms within 6 to 12 hours; these include excessive yawning, nausea and vomiting, chills, muscle aches, diarrhea, and insomnia—temporarily disrupting work, school, and social relationships. The symptoms can persist for 1 to 3 days, and the withdrawal process is completed in about a week.

Abuse of and dependence on heroin—the most commonly abused opiate—are reported in about a quarter million people in the United States (Substance Abuse and Mental Health Services Administration, 2009). Illicit use of opioid-containing prescription medicines has risen in recent years; one survey found that 9.3% of high school seniors reported using hydrocodone without a prescription and 5% used oxycodone (Johnston, Bachman, & Schulenberg, 2005). People who use opiates face risks beyond addiction and the threat of overdose. Because these drugs are usually injected intravenously, users are at increased risk for HIV infection and therefore AIDS.

The life of an opiate addict can be bleak. Results from a 33-year follow-up study of more than 80 addicts in an English town highlight a pessimistic view of many of their lives (Rathod, Addenbrooke, & Rosenbach, 2005). At the follow-up, 22% of addicts had died, about twice the national rate of about 12%. More than half the deaths were the result of drug overdose, and several took their own lives. The good news from this study was that of those who survived, 80% were no longer using opioids and the remaining 20% were being treated with methadone.

The high or "rush" experienced by users comes from activation of the body's natural opioid system. In other words, the brain already has its own opioids—called enkephalins and endorphins—that provide narcotic effects (Strain et al., 2009). Heroin, opium, morphine, and other opiates activate this system. The discovery of the natural opioid system was a major breakthrough in the field of psychopharmacology: Not only does it allow us to study the effects of addictive drugs on the brain, but it also has led to important discoveries that may help us treat people dependent on these drugs.

## Hallucinogens

The substances we have examined so far affect people by making them feel "up," if they are stimulants such as cocaine, caffeine, and nicotine, or "down," if they are depressants such as alcohol and the barbiturates. Next, we explore the substances that can lead to **hallucinogen use disorder**. They essentially change the way the user perceives the world. Sight, sound, feelings, taste, and even smell are distorted, sometimes in dramatic ways, when a person is under the influence of drugs such as marijuana and LSD.

### Marijuana

**Marijuana** was the drug of choice in the 1960s and early 1970s. Although it has decreased in popularity, it is still the most routinely used illegal substance, with 15.2 million Americans reporting they used the drug in the past month (Substance Abuse and Mental Health Services Administration, 2009). Marijuana is the name given to the dried parts of the cannabis or hemp plant (its full scientific name is ***Cannabis sativa***) (Hall & Degenhardt, 2009). Cannabis grows wild throughout the tropical and temperate regions of the world, which accounts for one of its nicknames, "weed."

As demonstrated by the following parable, people who smoke marijuana often experience altered perceptions of the world.

> Three men, so the story goes, arrived one night at the closed gates of a Persian city. One was intoxicated by alcohol, another was under the spell of opium, and the third was steeped in marihuana.
>
> The first blustered: “Let’s break the gates down.”
>
> “Nay,” yawned the opium eater, “let us rest until morning, when we may enter through the wide-flung portals.”
>
> “Do as you like,” was the announcement of the marihuana addict. “But I shall stroll in through the keyhole!” (Rowell & Rowell, 1939, p. 66)

Reactions to marijuana usually include mood swings. Otherwise-normal experiences seem extremely funny, or the person might enter a dreamlike state in which time seems to stand still. Users often report heightened sensory experiences, seeing vivid colors, or appreciating the subtleties of music. Perhaps more than any other drug, however, marijuana can produce different reactions in people. It is not uncommon for someone to report having no reaction to the first use of the drug; it also appears that people can “turn off” the high if they are sufficiently motivated (Hall & Degenhardt, 2009). The feelings of well-being produced by small doses can change to paranoia, hallucinations, and dizziness when larger doses are taken. High school–age marijuana smokers get lower grades and are less likely to graduate (Lynskey & Hall, 2000). Research on frequent marijuana users suggests that impairments of memory, concentration, relationships with others, and employment may be negative outcomes of long-term use, although some researchers suggest that some psychological problems precede usage—increasing the likelihood that someone will use marijuana (Macleod et al., 2004).

The evidence for marijuana tolerance is contradictory. Chronic and heavy users report tolerance, especially to the euphoric high (Mennes, Ben Abdallah, & Cottler, 2009); they are unable to reach the levels of pleasure they experienced earlier. However, evidence also indicates “reverse tolerance,” when regular users experience more pleasure from the drug after repeated use. Major signs of withdrawal do not usually occur with marijuana. Chronic users who stop taking the drug report a period of irritability, restlessness, appetite loss, nausea, and difficulty sleeping (National Institute on Drug Abuse, 2005).

Controversy surrounds the use of marijuana for medicinal purposes. However, there appears to be an increasing database documenting the successful use of marijuana and its by-products for the symptoms of certain diseases. In Canada, for example, four cannabis products are available for medical use, including an herbal cannabis extract (Sativex—delivered in a nasal spray), dronabinol (Marinol), nabilone (Cesamet), and the herbal form of cannabis that is typically smoked (Wang, Collet, Shapiro, & Ware, 2008). These cannabis-derived products are prescribed for chemotherapy-induced nausea and vomiting, HIV-associated anorexia, neuropathic pain in multiple sclerosis, and cancer pain. Unfortunately, marijuana smoke may contain as many carcinogens as tobacco smoke, and long-term use of the smoked form of the drug may contribute to diseases such as lung cancer. This potential health risk should be weighed against the benefits of using marijuana under certain medical circumstances.

Most marijuana users inhale the drug by smoking the dried leaves in marijuana cigarettes; others use preparations such as

hashish, which is the dried form of the resin in the leaves of the female plant. Marijuana contains more than 80 varieties of the chemicals called *cannabinoids,* which are believed to alter mood and behavior. The most common of these chemicals includes the *tetrahydrocannabinols,* otherwise known as *THC.* An exciting finding in the area of marijuana research is that the brain makes its own version of THC, a neurochemical called *anandamide* after the Sanskrit word *ananda,* which means "bliss" (Sedlak & Kaplin, 2009). Scientists are only beginning to explore how this neurochemical affects the brain and behavior.

## LSD and Other Hallucinogens

On a Monday afternoon in April 1943, Albert Hoffmann, a scientist at a large Swiss chemical company, prepared to test a newly synthesized compound. He had been studying derivatives of ergot, a fungus that grows on diseased kernels of grain, and sensed that he had missed something important in the 25th compound of the lysergic acid series. Ingesting what he thought was an infinitesimally small amount of this drug, which he referred to in his notes as LSD-25, he waited to see what subtle changes might come over him as a result. Thirty minutes later he reported no change, but some 40 minutes after taking the drug he began to feel dizzy and had a noticeable desire to laugh. Riding his bicycle home, he hallucinated that the buildings he passed were moving and melting. By the time he arrived home, he was terrified he was losing his mind. Hoffmann was experiencing the first recorded "trip" on LSD (Jones, 2009).

**LSD (*d*-lysergic acid diethylamide)**, sometimes referred to as "acid," is the most common hallucinogenic drug. It is produced synthetically in laboratories, although naturally occurring derivatives of this grain fungus (ergot) have been found historically. In Europe during the Middle Ages, an outbreak of illnesses occurred as a result of people's eating grain that was infected with the fungus. One version of this illness—later called *ergotism*—constricted the flow of blood to the arms or legs and eventually resulted in gangrene and the loss of limbs. Another type of illness resulted in convulsions, delirium, and hallucinations. Years later, scientists connected ergot with the illnesses and began studying versions of this fungus for possible benefits. This is the type of work Hoffmann was engaged in when he discovered LSD's hallucinogenic properties.

LSD remained in the laboratory until the 1960s, when it was first produced illegally for recreational use. The mind-altering effects of the drug suited the social effort to reject established culture and enhanced the search for enlightenment that characterized the mood and behavior of many people during that decade. The late Timothy Leary, at the time a Harvard University research professor, first used LSD in 1961 and immediately began a movement to have every child and adult try the drug and "turn on, tune in, and drop out."

There are a number of other hallucinogens, some occurring naturally in a variety of plants: *psilocybin* (found in certain species of mushrooms); *lysergic acid amide* (found in the seeds of the morning glory plant); *dimethyltryptamine (DMT)* (found in the bark of the Virola tree, which grows in South and Central America); and *mescaline* (found in the peyote cactus plant).

The *DSM-IV-TR* diagnostic criteria for hallucinogen intoxication are similar to those for marijuana: perceptual changes such as the subjective intensification of perceptions, depersonalization, and hallucinations. Physical symptoms include pupillary dilation, rapid heartbeat, sweating, and blurred vision (American Psychiatric Association, 2000). Many users have written about hallucinogens, and they describe a variety of experiences. In one well-designed placebo-controlled study of hallucinogens, researchers at Johns Hopkins School of Medicine gave volunteers either the hallucinogen psilocybin or a control drug (the ADHD medication Ritalin) and assessed their reactions (Griffiths, Richards, McCann, & Jesse, 2006). Psilocybin ingestion resulted in individualized reactions including perceptual changes (for example, mild visual hallucinations) and mood changes (for example, joy or happiness, anxiety, or fearfulness). Interestingly, the drug increased reports of mystical experiences (for example, deeply felt positive mood), and 2 months later many rated the experience as having a spiritual significance. More research is needed to explore how these types of drugs work, and this research may also tell us how our brains process experiences such as personal meaning and spirituality (Griffiths, Richards, Johnson, McCann, & Jesse, 2008).

Tolerance develops quickly to a number of hallucinogens, including LSD, psilocybin, and mescaline (Jones, 2009). If taken repeatedly over a period of days, these drugs lose their effectiveness. However, sensitivity returns after about a week of abstinence. For most hallucinogens, no withdrawal symptoms are reported. Even so, a number of concerns have been expressed about their use. One is the possibility of psychotic reactions. Stories in the popular press about people who jumped out of windows because they believed they could fly or who stepped into moving traffic with the mistaken idea that they couldn't be hurt have pro-

### DSM-IV-TR Table 11.12 Diagnostic Criteria for Hallucinogen Intoxication

**A.** Recent use of a hallucinogen.

**B.** Clinically significant maladaptive behavioral or psychological changes (e.g., marked anxiety or depression, ideas of reference, fear of losing one's mind, paranoid ideation, impaired judgment, or impaired social or occupational functioning) that developed during, or shortly after, hallucinogen use.

**C.** Perceptual changes occurring in a state of full wakefulness and alertness (e.g., subjective intensification of perceptions, depersonalization, derealization, illusions, hallucinations, synesthesia) that developed during, or shortly after, hallucinogen use.

**D.** Two (or more) of the following signs developing during, or shortly after, hallucinogen use:

1. Pupillary dilation
2. Tachycardia
3. Sweating
4. Palpitations
5. Blurring of vision
6. Tremors
7. Incoordination

**E.** The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder.

vided for sensational reading, but little evidence suggests that using hallucinogens produces a greater risk than being drunk or under the influence of any other drug. People do report having "bad trips"; these are the sort of frightening episodes in which clouds turn into threatening monsters or deep feelings of paranoia take over. Usually someone on a bad trip can be "talked down" by supportive people who provide constant reassurance that the experience is the temporary effect of the drug and it will wear off in a few hours.

We still do not fully understand how LSD and the other hallucinogens affect the brain. Most of these drugs bear some resemblance to neurotransmitters; LSD, psilocybin, lysergic acid amide, and DMT are chemically similar to serotonin; mescaline resembles norepinephrine; and a number of other hallucinogens we have not discussed are similar to acetylcholine. However, the mechanisms responsible for the hallucinations and other perceptual changes that users experience remain unknown.

## Other Drugs of Abuse

A number of other substances are used by individuals to alter sensory experiences. These drugs do not fit neatly into the classes of substances we just described but are nonetheless of great concern because they can be physically damaging to those who ingest them. We briefly describe inhalants, steroids, and a group of drugs commonly referred to as designer drugs.

Inhalants include a variety of substances found in volatile solvents—making them available to breathe into the lungs directly. Some common inhalants that are used abusively include spray paint, hair spray, paint thinner, gasoline, amyl nitrate, nitrous oxide ("laughing gas"), nail polish remover, felt-tipped markers, airplane glue, contact cement, dry-cleaning fluid, and spot remover (Sakai & Crowley, 2009). A typical person who engages in inhalant use tends to be male, Caucasian, live in rural or small towns, have higher levels of anxiety and depression, and show more impulsive and fearless temperaments (Perron & Howard, 2009). These drugs are rapidly absorbed into the bloodstream through the lungs by inhaling them from containers or on a cloth held up to the mouth and nose. The high associated with the use of inhalants resembles that of alcohol intoxication and usually includes dizziness, slurred speech, incoordination, euphoria, and lethargy (American Psychiatric Association, 2000). Users build up a tolerance to the drugs, and withdrawal—which involves sleep disturbance, tremors, irritability, and nausea—can last from 2 to 5 days. Unfortunately, use can also increase aggressive and antisocial behavior, and long-term use can damage bone marrow, kidneys, liver, and the brain (Sakai & Crowley, 2009).

Anabolic–androgenic steroids (more commonly referred to as steroids or "roids" or "juice") are derived from or are a synthesized form of the hormone testosterone (Pope & Brower, 2009). The legitimate medical uses of these drugs focus on people with asthma, anemia, breast cancer, and males with inadequate sexual development. However, the anabolic action of these drugs (that can produce increased body mass) has resulted in their illicit use by those wishing to bulk up and improve their physical abilities. Steroids can be taken orally or through injection, and some estimates suggest that approximately 2% of males will use the drug illegally at some point in their lives (Kanayama, Brower, Wood, Hudson, & Pope Jr., in press). Users sometimes administer the drug on a schedule of several weeks or months followed by a break from its use—called "cycling"—or combine several types of steroids—called "stacking." Steroid use differs from other drug use because the substance does not produce a desirable high but instead is used to enhance performance and body size. Dependence on the substance therefore seems to involve the desire to maintain the performance gains obtained rather than a need to reexperience an altered emotional or physical state. Research on the long-term effects of steroid use seems to suggest that mood disturbances are common (for example, depression, anxiety, and panic attacks) (Pope & Brower, 2009), and there is a concern that more serious physical consequences may result from regular use.

Another class of drugs—dissociative anesthetics—causes drowsiness, pain relief, and the feeling of being out of one's body (Javitt & Zukin, 2009). Sometimes referred to as designer drugs, this growing group of drugs was originally developed by pharmaceutical companies to target specific diseases and disorders. It was only a matter of time before some began using the developing technology to design "recreational drugs." We have already described one of the more common illicit designer drugs—MDMA, or Ecstasy—in the section on stimulants. This amphetamine is one of a small but feared growing list of related substances that

includes 3,4-methelenedioxyethamphetamine (MDEA, or Eve), and 2-(4-bromo-2,5-dimethoxy-phenyl)-ethylamine (BDMPEA, or Nexus) (Wu et al., 2009). Their ability to heighten a person's auditory and visual perception, as well as the senses of taste and touch, has been incorporated into the activities of those who attend nightclubs, all-night dance parties (raves), or large social gatherings of primarily gay men (called "circuit parties"). Phencyclidine (or PCP) is snorted, smoked, or injected intravenously, and it causes impulsivity and aggressiveness. A drug related to phencyclidine and associated with the "drug club" scene is ketamine (street names include K, Special K, and Cat Valium), a dissociative anesthetic that produces a sense of detachment, along with a reduced awareness of pain (Javitt & Zukin, 2009). Gamma-hydroxybutyrate (GHB, or liquid Ecstasy) is a central nervous system depressant that was marketed in health food stores in the 1980s as a means of stimulating muscle growth. Users report that, at low doses, it can produce a state of relaxation and increased tendency to verbalize but that at higher doses or with alcohol or other drugs it can result in seizures, severe respiratory depression, and coma. Use of all these drugs can result in tolerance and dependence, and their increasing popularity among adolescents and young adults raises significant public health concerns.

### Concept Check | 11.2

Determine whether the following statements about stimulants are true (T) or false (F).

1. __ Use of crack cocaine by a pregnant woman always adversely affects the developing fetus.
2. __ Regular use of stimulants can result in tolerance and dependence on the drugs.
3. __ Amphetamines have been used as appetite suppressants.
4. __ Compared to all other drugs, caffeine can produce the most variable reactions in people.
5. __ Amphetamines are naturally occurring drugs that induce feelings of elation and vigor and can reduce fatigue.
6. __ An ingredient of the beverage Coca-Cola in the 1800s was cocaine.
7. __ Stimulants are produced only in a laboratory.

## Causes of Substance-Related Disorders

People continue to use psychoactive drugs for their effects on mood, perception, and behavior despite the obvious negative consequences of abuse and dependence. We saw that despite his clear potential as an individual, Danny continued to use drugs to his detriment. Various factors help explain why people like Danny persist in using drugs. Drug abuse and dependence, once thought to be the result of moral weakness, are now understood to be influenced by a combination of biological and psychosocial factors.

Why do some people use psychoactive drugs without abusing or becoming dependent on them? Why do some people stop using these drugs or use them in moderate amounts after being dependent on them and others continue a lifelong pattern of dependence despite their efforts to stop? These questions continue to occupy the time and attention of numerous researchers throughout the world.

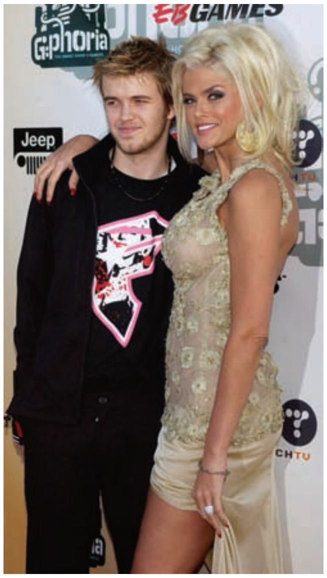
### Biological Dimensions

In 2007, when American model and television personality Anna Nicole Smith died from an apparently accidental overdose of at least nine prescription medications—including methadone, Valium, and the sedative chloral hydrate—the unfortunate news created a media sensation. The tragedy was compounded by the fact that, just months before, her only son Daniel had died, also from an apparent drug overdose. Did the son inherit a vulnerability to addiction from his mother? Did he pick up Anna Nicole's habits from living with her over the years? Is it just a coincidence that both mother and son were so involved with drugs?

#### *Familial and Genetic Influences*

As you already have seen throughout this book, many psychological disorders are influenced in important ways by genetics. Mounting evidence indicates that drug abuse follows this pattern. A great deal of animal research confirms the importance of genetic influences on substance abuse. In work with humans, researchers conducting twin, family, and adoption studies have found that certain people are genetically vulnerable to drug abuse (Strain, 2009). Twin studies of smoking, for example, indicate a moderate genetic influence (e.g., Hardie, Moss, & Lynch, 2006; McCaffery, Papandonatos, Stanton, Lloyd-Richardson, & Niaura, 2008). However, most genetic data on substance abuse come from research on alcoholism, which is widely studied because alcohol use is legal and many people are dependent on it. Research in general suggests that genetic risk factors cut across all mood-altering drugs (Strain, 2009).

In a major twin study, the role of the environment, as well as the role of genetics, was examined in substance use, abuse, and dependence. Researchers studied more than 1,000 pairs of male twins and questioned them about their use of marijuana, cocaine, hallucinogens, sedatives, stimulants, and opiates (Kendler, Jacobson, Prescott, & Neale, 2003). The findings—which may have major implications for how we approach treatment and prevention—suggest



©UPI Photo/Jim Ruymen/Landov

▲ Anna Nicole Smith and her son Daniel both died from drug complications, raising questions about how environment and biology played roles in their drug use.

that there are common genetic influences on the use of all of these drugs. However, the *use* of illegal drugs was primarily influenced by environmental factors, whereas *abuse and dependence* may be influenced primarily by genetic factors. Therefore, whether or not you use drugs such as cocaine or heroin may be a factor of whom and what you are exposed to, but whether you will become addicted is largely a function of your biology. As the search for the genes influencing substance use, abuse, and dependence continues, the next obvious question is how these genes function when it comes to addiction—a field of research called *functional genomics* (Khokhar, Ferguson, Zhu, & Tyndale, 2010).

Genetic research to date tells us that substance abuse in general is affected by our genes but no one gene causes substance abuse or dependence. Genetic factors may affect how people experience certain drugs, which in turn may partly determine who will or will not become abusers. Just to illustrate how complex these relationships can be, research has found that certain genes are associated with a greater likelihood of heroin addiction in Hispanic and African American populations (Nielsen et al., 2008).

### Neurobiological Influences

In general, the pleasurable experiences reported by people who use psychoactive substances partly explain why people continue to use them (Strain, 2009). In behavioral terms, people are positively reinforced for using drugs. But what mechanism is responsible for such experiences? Complex and fascinating studies indicate the brain appears to have a natural "pleasure pathway" that mediates our experience of reward. All abused substances seem to affect this internal reward center. In other words, what psychoactive drugs may have in common is their ability to activate this reward center and provide the user with a pleasurable experience, at least for a time.

The pleasure center was discovered more than 50 years ago by James Olds, who studied the effects of electrical stimulation on rat brains (Olds, 1956; Olds & Milner, 1954). If certain areas were stimulated with small amounts of electricity, the rats behaved as if they had received something pleasant, such as food. The exact location of the area in the human brain is still subject to debate, although it is believed to include the *dopaminergic system* and its *opioid-releasing neurons,* which begin in the midbrain *ventral tegmental area* and then work their way forward through the *nucleus accumbens* and on to the frontal cortex (Strain, 2009).

How do different drugs that affect different neurotransmitter systems all converge to activate the pleasure pathway, which is primarily made up of dopamine-sensitive neurons? Researchers are only beginning to sort out the answers to this question, but some surprising findings have emerged in recent years. For example, we know that amphetamines and cocaine act directly on the dopamine system. Other drugs, however, appear to increase the availability of dopamine in more roundabout and intricate ways. For example, the neurons in the brain's ventral tegmental area are kept from continuous firing by GABA neurons. (Remember that the GABA system is an inhibitory neurotransmitter system that blocks other neurons from sending information.) One thing that keeps us from being on an unending high is the presence of these GABA neurons, which act as the "brain police," or superegos of the reward neurotransmitter system. Opiates (opium, morphine, heroin) inhibit GABA, which in turn stops the GABA neurons from inhibiting dopamine, which makes more dopamine available in the brain's pleasure pathway. Drugs that stimulate the reward center directly or indirectly include not only amphetamine, cocaine, and opiates but also nicotine and alcohol (Strain, 2009).

This complicated picture is far from complete. We now understand that other neurotransmitters in addition to dopamine—including serotonin and norepinephrine—are also involved in the brain's reward system (Khokhar et al., 2010). The coming years should yield interesting insights into the interaction of drugs and the brain. One aspect that awaits explanation is how drugs not only provide pleasurable experiences (positive reinforcement) but also help remove unpleasant experiences such as pain, feelings of illness, or anxiety (negative reinforcement). Aspirin is a negative reinforcer: We take it not because it makes us feel good but because it stops us from feeling bad. In much the same way, one property of the psychoactive drugs is that they stop people from feeling bad, an effect as powerful as making them feel good.

With several drugs, negative reinforcement is related to the anxiolytic effect, the ability to reduce anxiety (discussed briefly in the section on the sedative, hypnotic, and anxiolytic drugs). Alcohol has an anxiolytic effect. The neurobiology of how these drugs reduce anxiety seems to involve the septal–hippocampal system (Gray, 1987), which includes a large number of GABA-sensitive neurons. Certain drugs may reduce anxiety by enhancing the activity of GABA in this region, thereby inhibiting the brain's normal reaction (anxiety or fear) to anxiety-producing situations (Gordis, 2000; Pihl, Peterson, & Lau, 1993). ■ Figure 11.8 illustrates how a drug such as nicotine has a multifaceted impact on a variety of neurotransmitter systems and in turn their effects on the experience of smoking.

Researchers have identified individual differences in the way people respond to alcohol. Understanding these response differences is important because they may help explain why some people continue to use drugs until they acquire a dependence on them, whereas others stop before this happens. A number of studies compare individuals with and without a family history of alcoholism (Gordis, 2000). They concluded that, compared to the sons of nonalcoholics, the sons of alcoholics may be more sensitive to alcohol when it is first ingested and then become less sensitive to its effects as the hours pass after drinking. This finding is significant because the euphoric effects of alcohol occur just after drinking but the experience after several hours is often sadness and depression. People who are at risk for developing alcoholism (in this case, the sons of alcoholics) may be better able to appreciate the initial highs of drinking and be less sensitive to the lows that come later, making them ideal candidates for continued drinking. In support of this observation, follow-up research over a 10-year period found that those men who tended to be less sensitive to alcohol also tended to drink more heavily and more often (Schuckit, 1994, 1998).

One current line of research involves analyzing the brain wave patterns of people at risk for developing alcoholism. This research is studying the sons of people with alcohol problems because of their own increased likelihood of having alcohol problems. Participants are asked to sit quietly and listen for a particular tone.

When they hear the tone, they are to signal the researcher. During this time, their brain waves are monitored and a particular pattern emerges called the *P300 amplitude.* Approximately 300 milliseconds (the origin of the "P300" designation) after the tone is presented, a characteristic spike in brain waves occurs that indicates the brain is processing this information. In general, researchers find this spike is lower among those with a family history of alcoholism (Schulte, Ramo, & Brown, 2009).

Is this brain wave difference somehow connected to the reasons people later develop a dependence on alcohol, or is it just a marker or sign that these individuals have in common but is not related to their drinking? One piece of evidence that argues against the P300 differences as a marker for alcoholism is that individuals with a variety of other substance use problems (for example, opioid users) and psychological disorders (for example, schizophrenia and depression) also show lower P300 amplitude than control participants (Singh, Basu, Kohli, & Prabhakar, 2009). Researchers are continuing to try to understand this interesting but puzzling phenomenon.

## Psychological Dimensions

We have shown that the substances people use to alter mood and behavior have unique effects. The high from heroin differs substantially from the experience of smoking a cigarette, which in turn differs from the effects of amphetamines or LSD. Nevertheless, it is important to point out the similarities in the way people mentally react to most of these substances.

### *Positive Reinforcement*

The feelings that result from using psychoactive substances are pleasurable in some way, and people will continue to take the drugs to recapture the pleasure. Research shows quite clearly that many drugs used and abused by humans also seem to be pleasurable to animals (Young & Herling, 1986). Laboratory animals will work to have their bodies injected with drugs such as cocaine, amphetamines, opiates, sedatives, and alcohol, which demonstrates that even without social and cultural influences these drugs are pleasurable.

Human research also indicates that to some extent all psychoactive drugs provide a pleasurable experience (Strain, 2009). In addition, the social contexts for drug taking may encourage its use, even when the use alone is not the desired outcome. One study found that among volunteers who preferred not to take Valium, pairing money with pill taking caused participants to switch from a placebo to Valium (Alessi, Roll, Reilly, & Johanson, 2002). Positive reinforcement in the use and the situations surrounding the use of drugs contributes to whether or not people decide to try to continue using drugs.

### *Negative Reinforcement*

Most researchers have looked at how drugs help reduce unpleasant feelings through negative reinforcement. Many people are likely to initiate and continue drug use to escape from unpleasantness in their lives. In addition to the initial euphoria, many drugs provide escape from physical pain (opiates), from stress (alcohol), or from panic and anxiety (benzodiazepines). This phenomenon has been explored under a number of different names, including *tension reduction, negative affect,* and *self-medication,* each of which has a somewhat different focus (Strain, 2009).

Basic to many views of abuse and dependence is the premise that substance use becomes a way for users to cope with the unpleasant feelings that go along with life circumstances. For example, one study of 1,252 U.S. Army soldiers returning home from Operation Iraqi Freedom found that those exposed to violent combat, human trauma, and having direct responsibility for taking the life of another person were at increased risk for risk-taking and for more frequent and greater alcohol use (Killgore et al., 2008). People who experience other types of trauma such as sexual abuse are also more likely to abuse alcohol (Ullman, Najdowski, & Filipas, 2009). These observations emphasize the important role played by each aspect of abuse and dependence—biological, psychological, social, and cultural—in determining who will and who will not have difficulties with these substances.

In a study that examined substance use among adolescents as a way to reduce stress (Chassin, Pillow, Curran, Molina, & Barrera, 1993), researchers compared a group of adolescents with alcoholic parents with a group whose parents did not have drinking problems. The average age of the adolescents was 12.7 years. The researchers found that just having a parent with alcohol dependence was a major factor in predicting who would use alcohol and other drugs. However, they also found that adolescents who reported negative affect, such as feeling lonely, crying a lot, or being tense, were more likely than others to use drugs. The researchers further determined that the adolescents from both groups tended to use drugs as a way to cope with unpleasant feelings. This study and others (see, for example, Pardini, Lochman, & Wells, 2004) suggest that one contributing factor to adolescent drug use is the desire to escape from unpleasantness. It also suggests that to prevent people from using drugs we may need to address influences such as stress and anxiety, a strategy we discuss in our section on treatment.

Many people who use psychoactive substances experience a crash after being high. If people reliably crash, why don't they just stop taking drugs? One explanation is given by Solomon and Corbit in an interesting integration of both the positive and the negative reinforcement processes (Solomon, 1980; Solomon & Corbit, 1974). The *opponent-process theory* holds that an increase in positive feelings will be followed shortly by an increase in negative feelings. Similarly, an increase in negative feelings will be followed by a period of positive feelings (Skinner & Aubin, 2010). Athletes often report feeling depressed after finally attaining a long-sought goal. The opponent-process theory claims that this mechanism is strengthened with use and weakened by disuse. So a person who has been using a drug for some time will need more of it to achieve the same results (tolerance). At the same time, the negative feelings that follow drug use tend to intensify. For many people, this is the point at which the motivation for drug taking shifts from desiring the euphoric high to alleviating the increasingly unpleasant crash. Unfortunately, the best remedy is more of the same drug. People who are hung over after drinking too much alcohol are often advised to have "the hair of the dog that bit you" (that is, have another drink). The sad irony here is that the very drug that can make you feel so bad is also the one thing that can take away your pain. You can see why people can become enslaved by this insidious cycle.

Researchers have also looked at substance abuse as a way of self-medicating for other problems. If people have difficulties with anxiety, for example, they may be attracted to barbiturates or alcohol because of their anxiety-reducing qualities. In one study, researchers were successful in treating a group of cocaine addicts who had ADHD with methylphenidate (Ritalin) (Levin, Evans, Brooks, & Garawi, 2007). They had hypothesized that these individuals used cocaine to help focus their attention. Once their ability to concentrate improved with the methylphenidate, the users reduced their use of cocaine. Research is just beginning to outline the complex interplay among stressors, negative feelings, other psychological disorders, and negative reactions to the drugs themselves as causative factors in psychoactive drug use.

## Cognitive Factors

What people expect to experience when they use drugs influences how they react to them. A person who expects to be less inhibited when she drinks alcohol will act less inhibited whether she actually drinks alcohol or a placebo she thinks is alcohol (Moss & Albery, 2009). This observation about the influence of how we think about drug use has been labeled an *expectancy effect* and has received considerable research attention.

Expectancies develop before people actually use drugs, perhaps as a result of parents' and peers' drug use, advertising, and media figures who model drug use (Campbell & Oei, 2010). In one study, a large group of seventh- and eighth-graders were given questionnaires that focused on their expectations about drinking. The researchers reexamined the students 1 year later to see how their expectancies predicted their later drinking (Christiansen, Smith, Roehling, & Goldman, 1989). One surprising finding was the marked increase in drinking among the students only 1 year later. When researchers first questioned them, about 10% of the students reported getting drunk two to four times per year. This number had risen to 25% by the next year. The students' expectations of drinking did predict who would later have drinking problems. Students who thought that drinking would improve their social behavior and their cognitive and motor abilities (despite all evidence to the contrary) were more likely to have drinking problems 1 year later. These results suggest that adolescents may begin drinking partly because they believe drinking will have positive effects.

Expectations appear to change as people have more experience with drugs, although their expectations are similar for alcohol, nicotine, marijuana, and cocaine (Simons, Dvorak, & Lau-Barraco, 2009). Some evidence points to positive expectancies—believing you will feel good if you take a drug—as an indirect influence on drug problems. In other words, what these beliefs may do is increase the likelihood you will take certain drugs, which in turn will increase the likelihood that problems will arise.

Once people stop taking drugs after prolonged or repeated use, powerful urges called "cravings" can interfere with efforts to remain off these drugs (Epstein, Marrone, Heishman, Schmittner, & Preston, 2010). If you've ever tried to give up ice cream and then found yourself compelled to have some, you have a limited idea of what it might be like to crave a drug. These urges seem to be triggered by factors such as the availability of the drug, contact with things associated with drug taking (for example, sitting in a bar), specific moods (for example, being depressed), or having a small dose of the drug. For example, one study used a virtual reality apparatus to simulate visual, auditory, and olfactory (an alcohol-dipped tissue) cues (Lee et al., 2009) for alcohol-dependent adults. The participants could choose among kinds of alcoholic beverages (e.g., beer, whiskey, or wine), snacks, and drinking environments (beer garden, restaurant, and pub). The researchers found significant increases in cravings for alcohol under these conditions (Lee et al., 2009). This type of technology may make it easier for clinicians to assess potential problem areas for clients, which can then be targeted to help keep them from relapsing. Research is under way to determine how cravings may work in the brain and if certain medications can be used to reduce these urges and help supplement treatment (Skinner & Aubin, 2010).

## Social Dimensions

Previously, we pointed out the importance of exposure to psychoactive substances as a necessary prerequisite to their use and possible abuse. You could probably list a number of ways people are exposed to these substances—through friends, through the media, and so on. For example, research on the consequences of cigarette advertising suggests the effects of media exposure may be more influential than peer pressure in determining whether teens smoke (Jackson, Brown, & L'Engle, 2007). One study looked at how, besides advertising, young children might be introduced to drugs (Noll, Zucker, & Greenberg, 1990). Children between the ages of 3 and 6 were given a smelling task at school. They were told to close their eyes and try to tell just by smelling what was in a jar. Nine different substances were presented to them: apple juice, Play-Doh, popcorn, coffee, perfume, beer, whiskey, wine, and cigarettes. Of the older children in this group, more than half could already recognize either beer, wine, or whiskey, and 20% of the youngest children were able to identify alcohol. The importance of this study is in its suggestion that many children are exposed to alcohol as preschoolers; it seems that they learn about alcohol from relatives and acquaintances rather than from television alone.

Research suggests that drug-addicted parents spend less time monitoring their children than parents without drug problems (Dishion, Patterson, & Reid, 1988) and that this is an important contribution to early adolescent substance use (Barnes, Hoffman, Welte, Farrell, & Dintcheff, 2006). When parents did not provide appropriate supervision, their children tended to develop friendships with peers who supported drug use. Children influenced by drug use at home may be exposed to peers who use drugs as well. A self-perpetuating pattern seems to be associated with drug use that extends beyond the genetic influences we discussed previously.

©Richard Newton/Alamy

▲ Many young children are exposed to drug use.

How does our society view people who are dependent on drugs? This issue is of tremendous importance because it affects efforts to legislate the sale, manufacture, possession, and use of these substances. It also dictates how drug-dependent individuals are treated. Two views of substance abuse and dependence characterize contemporary thought: the moral weakness and the disease models of dependence. According to the *moral weakness model of chemical dependence,* drug use is seen as a failure of self-control in the face of temptation; this is a psychosocial perspective. Proponents of this model see drug users as lacking the character or moral fiber to resist the lure of drugs. We saw earlier, for example, that the Catholic Church made drug abuse an official sin—an indication of its disdain. The *disease model of dependence,* in contrast, assumes that drug dependence is caused by an underlying physiological disorder; this is a biological perspective. Those who ascribe to this model think that just as diabetes or asthma can't be blamed on the afflicted individuals, neither should drug dependence. AA and similar organizations see drug dependence as an incurable disease over which the addict has no control (Kelly, Stout, Magill, Tonigan, & Pagano, 2010).

Neither perspective does justice to the complex interrelationship between the psychosocial and biological influences that affect substance disorders. Viewing drug use as moral weakness leads to punishing those afflicted with the disorder, whereas a disease model includes seeking treatment for a medical problem. Messages that the disorder is out of their control can at times be counterproductive. A comprehensive view of substance-related disorders that includes both psychosocial and biological influences is needed for this important societal concern to be addressed adequately.

### Cultural Dimensions

Culture is a pervasive factor in the influence of drug use and treatment. For example, the extent to which and how well people adapt to new cultures (*acculturation*) can be either a source of strength or a stress that can impact drug use. Cultural factors such as *machismo* (male dominance in Latin cultures), *marianismo* (female Latin role of motherly nurturance and identifying with the Virgin Mary), spirituality, and *tiu lien* ("loss of face" among Asians, that can lead to shame for not living up to cultural expectations) are just a few of the variations in outlook that can affect drug use and treatment in either a positive or negative way (Castro & Nieri, 2010). In addition, when we examine a behavior as it appears in different cultures, it is necessary to reexamine what is considered abnormal (Kohn, Wintrob, & Alarcon, 2009). Each culture has its own preferences for acceptable psychoactive drugs, as well as its own prohibitions for substances it finds unacceptable. Keep in mind that in addition to defining what is or is not acceptable, cultural norms affect the rates of substance abuse and dependence in important ways. For example, poor economic conditions in certain parts of the world limit the availability of drugs, which appears partly to account for the relatively low prevalence of substance abuse in Mexico and Brazil (de Almeidia-Filho, Santana, Pinto, & de Carvalho-Neto, 1991; Ortiz & Medicna-Mora, 1988).

On the other hand, in certain cultures, including Korea, people are expected to drink alcohol heavily on certain social occasions

(C. K. Lee, 1992). As we have seen before, exposure to these substances, in addition to social pressure for heavy and frequent use, may facilitate their abuse, and this may explain the high alcohol abuse rates in countries like Korea. This cultural influence provides an interesting natural experiment when exploring gene–environment interactions. People of Asian descent are more likely to have the ALDH2 gene, which produces a severe "flushing" effect (reddening and burning of the face) after drinking alcohol. This flushing effect was thought to be responsible for a relatively low rate of drinking in the population. However, between 1979 and 1992—when increased drinking became socially expected—there was an increase in alcohol abuse (Higuchi et al., 1994). The protective value of having the ALDH2 gene was diminished by the change in cultural norms (Rutter, Moffit, & Caspi, 2006).

Cultural factors not only influence the rates of substance abuse but also determine how it is manifest. Research indicates that alcohol consumption in Poland and Finland is relatively low, yet conflicts related to drinking and arrests for drunkenness in those countries are high compared to those in the Netherlands, which has about the same rate of alcohol consumption (Osterberg, 1986). Our discussion of expectancies may provide some insight into how the same amount of drinking can have different behavioral outcomes. Expectancies about the effects of alcohol use differ across cultures (for example, "Drinking makes me more aggressive" versus "Drinking makes me more withdrawn"); these differing expectancies may partially account for the variations in the consequences of drinking in Poland, Finland, and the Netherlands. Whether substance use is considered a harmful dysfunction often depends on the assumptions of the cultural group.

## An Integrative Model

Any explanation of substance use, abuse, and dependence must account for the basic issue raised earlier in this chapter: Why do some people use drugs but not abuse them or become dependent? ■ Figure 11.9 illustrates how the multiple influences we have discussed may interact to account for this process. Access to a drug is a necessary but not a sufficient condition for abuse or dependence. Exposure has many sources, including the media, parents, peers, and, indirectly, lack of supervision. Whether people use a drug depends also on social and cultural expectations, some encouraging and some discouraging, such as laws against possession or sale of the drug.

The path from drug use to abuse and dependence is more complicated (see Figure 11.9). As major stressors aggravate many disorders we have discussed, so do they increase the risk of abuse and dependence on psychoactive substances. Genetic influences may be of several types. Some individuals may inherit a greater sensitivity to the effects of certain drugs; others may inherit an ability to metabolize substances more quickly and are thereby able to tolerate higher (and more dangerous) levels. Other psychiatric conditions may indirectly put someone at risk for substance abuse. Antisocial personality disorder, characterized by the frequent violation of social norms (see Chapter 12), is thought to include a lowered rate of arousal; this may account for the increased prevalence of substance abuse in this group. People with mood disorders or anxiety disorders may self-medicate by using drugs to relieve the negative symptoms of their disorder, and this may account for the high rates of substance abuse in this group.

We know also that continued use of certain substances changes the way our brains work through a process called *neuroplasticity*. We tend to think of neuroplasticity—the brain's tendency to reorganize itself by forming new neural connections—when we hear stories of people recovering abilities after some brain damage. This ability to adapt to change is something we hope for when injury occurs to the brain. The other side of this ability shows itself in drug addiction. With the continued use of substances such as alcohol, cocaine, or the other drugs we explore in this chapter, the brain reorganizes itself to adapt. Unfortunately, this change in the brain increases the drive to obtain the drug and decreases the desire for other nondrug experiences—both of which contribute to continued use and relapse (Russo, Mazei-Robison, Ables, & Nestler, 2009).

It is clear that abuse and dependence cannot be predicted from one factor, be it genetic, neurobiological, psychological, or cultural. For example, *some* people with the genes common to many with substance abuse problems do not become abusers. Many people who experience the most crushing stressors, such as abject poverty or bigotry and violence, cope without resorting to drug use. There are different pathways to abuse, and we are only now beginning to identify their basic outlines.

Once a drug has been used repeatedly, biology and cognition conspire to create dependence. Continual use of most drugs causes tolerance, which requires the user to ingest more of the drug to produce the same effect. Conditioning is also a factor. If pleasurable drug experiences are associated with certain settings, a return to such a setting will later

cause urges to develop, even if the drugs themselves are not available.

This complex picture still does not convey the intricate lives of people who develop substance-related disorders. Each person has a story and path to abuse and dependence. We have only begun to discover the commonalities of substance disorders; we need to understand a great deal more about how all the factors interact to produce them.

## Concept Check 11.3

### Part A

Match the following descriptions with their corresponding stimulants: (a) opioids, (b) amphetamines, (c) cocaine, (d) hallucinogens, (e) nicotine, and (f) caffeine.

1. This is the most common psychoactive substance because it is legal, elevates mood, and decreases fatigue. It's readily available in many beverages. ______________
2. This substance causes euphoria, appetite loss, and increased alertness. Dependence appears after years of use. Mothers addicted to this have the potential to give birth to irritable babies. ______________
3. These drugs, including LSD, influence perception, distorting feelings, sights, sounds, and smells. _________________________
4. These lead to euphoria, drowsiness, and slowed breathing. These substances are analgesics, relieving pain. Users tend to be secretive, preventing a great deal of research in this area. ______________
5. This substance stimulates the nervous system and relieves stress. The *DSM-IV-TR* describes withdrawal symptoms instead of an intoxication pattern. ______________
6. These create feelings of elation and vigor and reduce fatigue. They are prescribed to people with narcolepsy and ADHD. ______________

### Part B

Indicate whether these statements about the causes of substance-related disorders are true (T) or false (F).

7. ______ Negative reinforcement is involved in the continuance of drug use because drugs often provide escape from pain, stress, panic, and so on.
8. ______ Research with both animals and humans indicates that substance abuse in general is affected by our genes, although not one particular gene.
9. ______ The media and parental influences have no effect on adolescent drug use; it is solely a peer pressure factor.
10. ______ The expectancy effect is illustrated when a person who expects to be less inhibited when drinking alcohol is given a placebo and acts or feels normally.
11. ______ To some extent, all psychoactive drugs provide a pleasurable experience, creating positive reinforcement.

## Treatment of Substance-Related Disorders

When we left Danny, he was in jail, awaiting the legal outcome of being arrested for vehicular manslaughter. At this point in his life, Danny needs more than legal help; he needs to free himself from his addiction to alcohol and cocaine. And the first step in his recovery has to come from him. Danny must admit he needs help, that he does indeed have a problem with drugs, and that he needs others to help him overcome his chronic dependence. The personal motivation to work on a drug problem appears to be essential in the treatment of substance abuse (Miller, 2009). A therapist cannot help someone who doesn't want to change, and this can be a problem in treating substance abuse just as it is for people with disorders such as anorexia nervosa and antisocial personality disorder. Unfortunately, although Danny's arrest seemed to shock him into realizing how serious his problems had become, he was not ready to confront them head-on. He spent many hours researching how the antidepressant medication he was also taking could have caused the deadly accident and did not own up to his drug use as the cause.

Treating people who have substance-related disorders is a difficult task. Perhaps because of the combination of influences that often work together to keep people hooked, the outlook for those who are dependent on drugs is often not positive. You will see in the case of heroin dependence, for example, that a best-case scenario is often just trading one addiction (heroin) for another (methadone). And even people who successfully cease taking drugs may feel the urge to resume drug use all their lives.

Treatment for substance-related disorders focuses on multiple areas. Sometimes the first step is to help someone through the withdrawal process; typically, the ultimate goal is abstinence. In other situations, the goal is to get a person to maintain a certain level of drug use without escalating its intake, and sometimes it is geared toward preventing exposure to drugs. Because substance abuse arises from so many influences, it should not be surprising that treating people with substance-related disorders is not a simple matter of finding just the right drug or the best way to change thoughts or behavior.

Importantly, it is estimated that fewer than 25% of the people who have significant problems with substance use seek treatment for their problems (Dawson et al., 2005). In order to reach out to these individuals, efforts are under way to put in place routine screenings for substance-related problems in settings such as doctor's offices, hospital emergency rooms, and even in college and university health clinics. This community-wide approach is an important part of identifying difficulties and bringing treatment to those in need (Tucker, Murphy, & Kertesz, in press).

We discuss the treatment of substance-related disorders as a group because treatments have so much in common. For example, many programs that treat people for dependence on a variety of substances also teach skills for coping with life stressors. Some biological treatments focus on how to cancel out the effects of the ingested substances. We discuss the obvious differences among substances as they arise.

### Biological Treatments

There have been a variety of biologically based approaches designed primarily to change the way substances are experienced. In other words, scientists are trying to find ways to prevent people from experiencing the pleasant highs associated with drug use or to find alternative substances that have some of the positive effects (for example, reducing anxiety) without their addictive properties. Table 11.1 lists the current recommended medical treatments for many of the more intractable substance dependence problems.

#### Agonist Substitution

Increased knowledge about how psychoactive drugs work on the brain has led researchers to explore ways of changing how they are experienced by people who are dependent on them. One

**TABLE 11.1** Medical Treatments

| Substance | Treatment Goal | Treatment Approach |
|---|---|---|
| Nicotine | Reduce withdrawal symptoms and cravings | Nicotine replacement therapy (patch, gum, spray, lozenge, and inhaler) |
| | Reduce withdrawal symptoms and cravings | Bupropion (Zyban) |
| Alcohol | Reduce reinforcing effects of alcohol | Naltrexone |
| | Reduce alcohol craving in abstinent individuals | Acamprosate (Campral) |
| | Maintenance of abstinence | Disulfiram (Antabuse) |
| Marijuana | | No specific medical interventions recommended |
| Cocaine | | No specific medical interventions recommended |
| Opioids | Maintenance of abstinence | Methadone |
| | Maintenance of abstinence | Buprenorphine (Subutex) |

*Source:* From American Psychiatric Association. (2007). Practice guidelines for the treatment of patients with substance use disorders (2nd ed.). *American Journal of Psychiatry, 164*(Suppl.), 1–14.

method, **agonist substitution**, involves providing the person with a safe drug that has a chemical makeup similar to the addictive drug (therefore the name *agonist*). *Methadone* is an opiate agonist that is often given as a heroin substitute (e.g., Schwartz et al., 2009). Methadone is a synthetic narcotic developed in Germany during World War II when morphine was not available for pain control; it was originally called *adolphine* after Adolph Hitler (Martínez-Fernández, 2002). Although it does not give the quick high of heroin, methadone initially provides the same analgesic (pain reducing) and sedative effects. However, when users develop a tolerance for methadone it loses its analgesic and sedative qualities. Because heroin and methadone have *cross-tolerance,* meaning they act on the same neurotransmitter receptors, a heroin addict who takes methadone may become addicted to the methadone instead, but this is not always the case (Maremmani et al., 2009). Research suggests that when addicts combine methadone with counseling, many reduce their use of heroin and engage in less criminal activity (Schwartz et al., 2009). A newer agonist—buprenorphine—blocks the effects of opiates and seems to encourage better compliance than would a nonopiate or opiate antagonist (Strain et al., 2009).

Addiction to cigarette smoking is also treated by a substitution process. The drug—nicotine—is provided to smokers in the form of gum, patch, inhaler, or nasal spray, which lack the carcinogens included in cigarette smoke; the dose is later tapered off to lessen withdrawal from the drug. In general, these replacement strategies successfully help people stop smoking, although they work best with supportive psychological therapy (Hughes, 2009). People must be taught how to use the gum properly, and a portion of the people who successfully quit smoking become dependent on the gum itself (Etter, 2009). The nicotine patch, which requires less effort and provides a steadier nicotine replacement, may be somewhat more effective in helping people quit smoking (Hughes, 2009). Another medical treatment for smoking—*bupropion (Zyban)*—is also commonly prescribed, under the trade name *Wellbutrin,* as an antidepressant. This drug curbs the cravings without being an agonist for nicotine (rather than helping smokers trying to quit by making them less depressed).

### Antagonist Treatments

We described how many psychoactive drugs produce euphoric effects through their interaction with the neurotransmitter systems in the brain. What would happen if the effects of these drugs were blocked so that the drugs no longer produced the pleasant results? Would people stop using the drugs? **Antagonist drugs** block or counteract the effects of psychoactive drugs, and a variety of drugs that seem to cancel out the effects of opiates have been used with people dependent on a variety of substances. The most often prescribed opiate-antagonist drug, *naltrexone,* has had only limited success with individuals who are not simultaneously participating in a structured treatment program (Krupitsky & Blokhina, 2010). When it is given to a person who is dependent on opiates, it produces immediate withdrawal symptoms, an extremely unpleasant effect. A person must be free from these withdrawal symptoms completely before starting naltrexone, and because it removes the euphoric effects of opiates, the user must be highly motivated to continue treatment. *Acamprosate* also seems to decrease cravings in people dependent on alcohol, and it works best with highly motivated people who are also participating in psychosocial interventions (Kennedy et al., 2010). The brain mechanisms for the effects of this drug are not well understood (Oslin & Klaus, 2009).

Overall, naltrexone or the other drugs being explored are not the magic bullets that would shut off the addict's response to psychoactive drugs and put an end to dependence. They do appear to help some drug abusers handle withdrawal symptoms and the cravings that accompany attempts to abstain from drug use; antagonists may therefore be a useful addition to other therapeutic efforts.

### Aversive Treatment

In addition to looking for ways to block the euphoric effects of psychoactive drugs, clinicians in this area may prescribe drugs that make ingesting the abused substances extremely unpleasant. The expectation is that a person who associates the drug with feelings of illness will avoid using the drug. The most commonly known aversive treatment uses *disulfiram (Antabuse)* with people who are alcohol dependent (Ivanov, 2009). Antabuse prevents the breakdown of acetaldehyde, a by-product of alcohol, and the resulting buildup of acetaldehyde causes feelings of illness. People who drink alcohol after taking Antabuse experience nausea, vomiting, and elevated heart rate and respiration. Ideally, Antabuse is taken each morning, before the desire to drink arises. Unfortunately, noncompliance is a major concern, and a person who skips the Antabuse for a few days is able to resume drinking.

Efforts to make smoking aversive have included the use of *silver nitrate* in lozenges or gum. This chemical combines with the saliva of a smoker to produce a bad taste in the mouth. Research has not shown it to be particularly effective (Jensen, Schmidt, Pedersen, & Dahl, 1991). Both Antabuse for alcohol abuse and silver nitrate for cigarette smoking have generally been less than successful as treatment strategies on their own, primarily because they require that people be extremely motivated to continue taking them outside the supervision of a mental health professional.

### Other Biological Approaches

Medication is often prescribed to help people deal with the often-disturbing symptoms of withdrawal. *Clonidine,* developed to treat hypertension, has been given to people withdrawing from opiates. Because withdrawal from certain prescribed medications such as sedative drugs can cause cardiac arrest or seizures, these drugs are gradually tapered off to minimize dangerous reactions. In addition, sedative drugs (benzodiazepines) are often prescribed to help minimize discomfort for people withdrawing from other drugs, such as alcohol (Sher, Martinez, & Littlefield, in press).

## Psychosocial Treatments

Most biological treatments for substance abuse show some promise with people who are trying to eliminate their drug habit. However, not one of these treatments alone is successful for most people (Schuckit, 2009b). Most research indicates a need for social support or therapeutic intervention. Because so many people need help to overcome their substance disorder, a number of models and programs have been developed. Unfortunately, in no other area of psychology have unvalidated and untested methods of treatment been so widely accepted. A reminder: A program that has not been subject to the scrutiny of research *may* work, but the sheer number of people receiving services of unknown value is still cause for concern. We next review several therapeutic approaches that *have* been evaluated.

### Inpatient Facilities

The first specialized facility for people with substance abuse problems was established in 1935, when the first federal narcotic "farm" was built in Lexington, Kentucky. Now mostly privately run, such facilities are designed to help people get through the initial withdrawal period and to provide supportive therapy so that they can go back to their communities (Morgan, 1981). Inpatient care can be extremely expensive (Bender, 2004). The question arises, then, as to how effective this type of care is compared to outpatient therapy that can cost 90% less. Research suggests there may be no difference between intensive residential setting programs and quality outpatient care in the outcomes for alcoholic patients (Miller & Hester, 1986) or for drug treatment in general (Guydish, Sorensen, Chan, Werdegar, & Acampora, 1999; Smith, Kraemer, Miller, DeBusk, & Taylor, 1999). Although some people do improve as inpatients, they may do equally well in outpatient care that is significantly less expensive.

### Alcoholics Anonymous and Its Variations

Without question, the most popular model for the treatment of substance abuse is a variation of the Twelve Steps program first developed by AA. Established in 1935 by two alcoholic professionals, William "Bill W." Wilson and Robert "Dr. Bob" Holbrook Smith, the foundation of AA is the notion that alcoholism is a disease and alcoholics must acknowledge their addiction to alcohol and its destructive power over them. The addiction is seen as more powerful than any individual; therefore, they must look to a higher power to help them overcome their shortcomings. Central to the design of AA is its independence from the established medical community and the freedom it offers from the stigmatization of alcoholism (Denzin, 1987; Robertson, 1988). An important component is the social support it provides through group meetings.

Since 1935, AA has steadily expanded to include almost 106,000 groups in more than 100 countries (White & Kurtz, 2008). In one survey, 9% of the adult population in the United States reported they had at one time attended an AA meeting (Room & Greenfield, 2006). The Twelve Steps of AA are the basis of its philosophy (see Table 11.2). In them, you can see the reliance on prayer and a belief in God.

Reaction is rarely neutral to AA and similar organizations, such as Cocaine Anonymous and Narcotics Anonymous (Miller, Gold, & Pottash, 1989). Many people credit the approach with saving their lives, whereas others object that its reliance on spirituality and its adoption of a disease model fosters dependence. Because participants attend meetings anonymously and only when they feel the need to, conducting systematic research on its effectiveness has been unusually difficult (Miller & McCrady, 1993). Nevertheless, there have been numerous attempts to evaluate AA's effect on alcoholism (Ferri, Amato, & Davoli, 2006). Although there are not enough data to show what percentage of people abstain from using alcohol as a result of participating in AA, research finds that those people who regularly participate in AA activities—or other similar supportive approaches—and follow its guidelines carefully are more likely to have a positive outcome (Moos & Moos, 2007). AA can be an effective treatment for highly motivated people with alcohol dependence. We do not yet know, however, who is likely to succeed and who is likely to fail in AA. Other groups now exist (e.g., Rational Recovery, Moderation Management, Women for Sobriety, SMART Recovery) for individuals who benefit from the social support of others but who may not want the abstinence-oriented 12-step program offered by groups modeled after AA (Tucker et al., in press).

**TABLE 11.2** Twelve Suggested Steps of Alcoholics Anonymous

1. We admitted we were powerless over alcohol—that our lives had become unmanageable.
2. Came to believe that a power greater than ourselves could restore us to sanity.
3. Made a decision to turn our will and our lives over to the care of God as we understood Him.
4. Made a searching and fearless moral inventory of ourselves.
5. Admitted to God, to ourselves, and to another human being the exact nature of our wrongs.
6. Were entirely ready to have God remove all these defects of character.
7. Humbly asked Him to remove our shortcomings.
8. Made a list of all persons we had harmed, and became willing to make amends to them all.
9. Made direct amends to such people wherever possible, except when to do so would injure them or others.
10. Continued to take personal inventory and, when we were wrong, promptly admitted it.
11. Sought through prayer and meditation to improve our conscious contact with God as we understood Him, praying only for knowledge of His will for us and the power to carry that out.
12. Having had a spiritual awakening as the result of these steps, we tried to carry this message to alcoholics and to practice these principles in all our affairs.

*Source:* The Twelve Steps are reprinted with permission of Alcoholics Anonymous World Services (AAWS). Permission to reprint the Twelve Steps does not mean that AAWS has reviewed or approved the contents of the publication or that AAWS necessarily agrees with the views expressed herein. AA is a program of recovery from alcoholism only—use of the Twelve Steps in connection with programs and activities which are patterned after AA, but which address other problems, or in any other non-AA context, does not imply otherwise.

### Controlled Use

One of the tenets of AA is total abstinence; recovering alcoholics who have just one sip of alcohol are believed to have "slipped" until they again achieve abstinence. However, some researchers question this assumption and believe at least a portion of abusers of several substances (notably alcohol and nicotine) may be capable of becoming social users without resuming their abuse of these drugs.

In the alcoholism treatment field, the notion of teaching people **controlled drinking** is extremely controversial, partly because of a classic study showing partial success in teaching severe abusers to drink in a limited way (Sobell & Sobell, 1978). The participants were 40 male alcoholics in an alcoholism treatment program at a state hospital who were thought to have a good prognosis. The men were assigned either to a program that taught them how to drink in moderation (experimental group) or to a group that was abstinence oriented (control group). The researchers, Mark and Linda Sobell, followed the men for more than 2 years, maintaining contact with 98% of them. During the second year after treatment, those who participated in the controlled drinking group were functioning well 85% of the time, whereas the men in the abstinence group were reported to be doing well only 42% of the time. Although results in the two groups differed significantly, some men in both groups suffered serious relapses and required rehospitalization and some were incarcerated. The results of this study suggest that controlled drinking may be a viable alternative to abstinence for some alcohol abusers, although it clearly isn't a cure.

The controversy over this study began with a paper published in the prestigious journal *Science* (Pendery, Maltzman, & West, 1982). The authors reported they had contacted the men in the Sobell study after 10 years and found that only 1 of the 20 men in the experimental group maintained a pattern of controlled drinking. Although this reevaluation made headlines and was the subject of a segment on the *60 Minutes* television show, it had a number of flaws (Marlatt, Larimer, Baer, & Quigley, 1993). Most serious was the lack of data on the abstinence group over the same 10-year follow-up period. Because no treatment study on substance abuse pretends to help everyone who participates, control groups are added to compare progress. In this case, we need to know how well the controlled drinking group fared compared to the abstinence group.

The controversy over the Sobell study still has a chilling effect on controlled drinking as a treatment of alcohol abuse in the United States. In contrast, controlled drinking is widely accepted as a treatment for alcoholism in the United Kingdom. Despite opposition, research on this approach has been conducted in the ensuing years (e.g., Orford & Keddie, 2006), and the results seem to show that controlled drinking is at least as effective as abstinence but that neither treatment is successful for 70% to 80% of patients over the long term—a rather bleak outlook for people with alcohol dependence problems.

### Component Treatment

Most comprehensive treatment programs aimed at helping people with substance abuse and dependence problems have a number of components thought to boost the effectiveness of the "treatment package." We saw in our review of biological treatments that their effectiveness is increased when psychologically based therapy is added. In aversion therapy, which uses a conditioning model, substance use is paired with something extremely unpleasant, such as a brief electric shock or feelings of nausea. For example, a person might be offered a drink of alcohol and receive a painful shock when the glass reaches his lips. The goal is to counteract the positive associations with substance use with negative associations. The negative associations can also be made by imagining unpleasant scenes in a technique called *covert sensitization* (Cautela, 1966); the person might picture herself beginning to snort cocaine and be interrupted with visions of herself becoming violently ill (Kearney, 2006).

One component that seems to be a valuable part of therapy for substance use is *contingency management* (Higgins et al., 2008). Here, the clinician and the client together select the behaviors that the client needs to change and decide on the reinforcers that will reward reaching certain goals, perhaps money or small retail items like CDs. In a study of cocaine abusers, clients received cash vouchers (up to almost $2,000) for having cocaine-negative urine specimens (Higgins et al., 2006). This study found greater abstinence rates among cocaine-dependent users with the contingency management approach and other skills training than among users in a more traditional counseling program that included a 12-step approach to treatment.

Another package of treatments is the *community reinforcement approach* (Higgins, Sigmon, & Heil, 2008). In keeping with the multiple influences that affect substance use, several facets of the drug problem are addressed to help identify and correct aspects of the person's life that might contribute to substance use or interfere with efforts to abstain. First, a spouse, friend, or relative who is not a substance user is recruited to participate in relationship therapy to help the abuser improve relationships with other important people. Second, clients are taught how to identify the antecedents and consequences that influence their drug taking. For example, if they are likely to use cocaine with certain friends, clients are taught to recognize the relationships and encouraged to avoid the associations. Third, clients are given assistance with employment, education, finances, or other social service areas that may help reduce their stress. Fourth, new recreational options help the person replace substance use with new activities. There is now strong empirical support for the effectiveness of this approach with alcohol and cocaine abusers (Higgins et al., 2008).

Obstacles to successful treatment for substance use and dependence include a lack of personal awareness that one has a problem and an unwillingness to change. An increasingly common intervention approach that directly addresses these needs is referred to as *motivational interviewing* (Miller, 2009). Motivational interviewing (MI) is based on the work of Miller and Rollnick (2002), who proposed that behavior change in adults is more likely with empathetic and optimistic counseling (the therapist understands the client's perspective and believes that he or she can change) and a focus on a personal connection with the client's core values (for example, drinking and its consequences interferes with spending more time with family). By reminding the client about what he or she cherishes most, MI intends to improve the individual's belief that any changes made (e.g., drinking less) will have positive outcomes (e.g., more family time) and the individual is therefore more likely to make the recommended changes. Motivational interviewing has been used to assist individuals with a variety of substance use problems, and it appears to be a useful component to add to psychological treatment (Lundahl, Kunz, Brownell, Tollefson, & Burke, 2010).

Cognitive-behavioral therapy (CBT) is an effective treatment approach for many psychological disorders (see Chapter 5, for example) and it is also one of the most well designed and studied approaches for treating substance dependence (Carroll, 2008; Sher et al., in press). This treatment addresses multiple aspects of the disorder, including a person's reactions to cues that lead to substance use (for example, being among certain friends) (Ferguson & Shiffman, 2009) and thoughts and behaviors to resist use (Wiers et al., in press). Another target of CBT addresses the problem of relapse. Marlatt and Gordon's (1985) **relapse prevention** treatment model looks at the learned aspects of dependence and sees relapse as a failure of cognitive and behavioral coping skills (Witkiewitz & Marlatt, 2004). Therapy involves helping people remove any ambivalence about stopping their drug use by examining their beliefs about the positive aspects of the drug ("There's nothing like a cocaine high") and confronting the negative consequences of its use ("I fight with my wife when I'm high"). High-risk situations are identified ("having extra money in my pocket"), and strategies are developed to deal with potentially problematic situations, as well as with the craving that arises from abstinence. Incidents of relapse are dealt with as occurrences from which the person can recover; instead of looking on these episodes as inevitably leading to more drug use, people in treatment are encouraged to see them as episodes brought on by temporary stress or a situation that can be changed. Research on this technique suggests that it may be particularly effective for alcohol problems (Irvin, Bowers, Dunn, & Wang, 1999), as well as in treating a variety of other substance use disorders (see, for example, Burleson & Kaminer, 2005).

## Prevention

Over the past few years, the strategies for preventing substance abuse and dependence have shifted from education-based approaches (for example, teaching schoolchildren that drugs can be harmful) to more wide-ranging approaches, including changes in the laws regarding drug possession and use and community-based interventions (Sher et al., in press). Many states, for example, have implemented education-based programs in schools to try to deter students from using drugs. The widely used Drug Abuse Resistance Education (DARE) program encourages a "no drug use" message through fear of consequences, rewards for commitments not to use drugs, and strategies for refusing offers of drugs. Unfortunately, several extensive evaluations suggest that this type of program may not have its intended effects (Pentz, 1999). Fortunately, more comprehensive programs that involve skills training to avoid or resist social pressures (such as peers) and environmental pressures (such as media portrayals of drug use) can be effective in preventing drug abuse among some. For example, one large-scale longitudinal study used a community-based intervention strategy to reduce binge drinking and alcohol-related injuries (for example, car crashes and assaults) (Holder et al., 2000). Three communities were mobilized to encourage responsible beverage service (that is, not serving too much alcohol to bar patrons), limit alcohol access to underage drinkers, and increase local enforcement of drinking and driving laws to limit access to alcohol. People's self-reports of drinking too much and drinking and driving were fewer after the intervention, as were alcohol-

## Innovative Approaches

### Two New Paths to Prevention

We see that the problem with drug abuse is not just use of the drug. A complicating factor in drug abuse includes the brain's desire to continue to use the drug, especially when in the presence of stimuli and situations usually associated with the drug. This "drug seeking" and relapse continue to interfere with successful treatment. Groundbreaking research is now exploring where in the brain these processes occur, which in turn may lead to new approaches to help people remain drug free (Kalivas, 2005).

Taking this one step further, new research with animals suggests the possibility of creating "vaccines" that would use the immune system to fight drugs such as heroin, just as your body attacks infectious bacteria (Anton & Leff, 2006). A vaccine that would take away the pleasurable aspects of smoking is now being tested with humans (Moreno, et al., 2010). What this means is that—theoretically—children could be vaccinated early in their lives and that if they tried a drug it would not have the pleasurable effects that would encourage repeated use. These "vice vaccines" could hold the answer to one of our most pressing social issues.

On the other end of the intervention spectrum, new and more comprehensive prevention approaches may help many individuals avoid initially trying dangerous drugs. One such approach is being used in Montana—called the Montana Meth Project (Generations United, 2006). Initially funded by software billionaire Timothy Siegel, this initiative supports advertising and community action programs to inform youth across the state about the devastating effects of methamphetamine use. The project uses dramatic and sometimes shocking pictures and video ads, and its surveys suggest that the methods were successful in changing attitudes about meth use in many 12- to 17-year-olds. Although no controlled research yet exists, this may be an additional powerful tool for reducing drug dependence.

▲ The Montana Meth Project used photos like these from Faces of Meth, a project of the Multnomah County Sheriff's Office in Portland, Oregon.

related car accidents and assaults. These types of comprehensive programs may need to be replicated across communities and extended to more pervasive influences (for example, how drug use is portrayed in the media) to effect significant prevention results.

It may be that our most powerful preventive strategy involves cultural change. Over the past 25 years or so, we have gone from a "turn on, tune in, drop out," "if it feels good, do it," and "I get high with a little help from my friends" society to one that champions statements like "Just say no to drugs." The social unacceptability of excessive drinking, smoking, and other drug use is probably responsible for this change. The sociocultural disapproval of cigarette smoking, for example, is readily apparent in the following description by a former smoker:

> I began smoking (in Boy Scouts!) at age 11. By the time I was a college freshman, freed from the restrictions of school and home, my smoking had increased to a pack a day. The seminal Surgeon General's Report *Smoking and Health* was issued that year (1964), but I didn't notice. The warnings that began appearing on cigarette packs a couple of years later were also easy to ignore, since I had grown up knowing that smoking was unhealthy. As a graduate student and young professor I often smoked while leading class discussions, as had some of my favorite teachers. That ended in 1980, when an undergraduate student, no doubt empowered by the antismoking movement, asked me to stop because smoke bothered him. A few years later there were hardly any social situations left in which it was acceptable to smoke. Even my home was no longer a refuge, since my children were pestering me to quit. And so I did. Now my status as former smoker puts me in company with fully half of all those who have ever smoked regularly and are alive today. For many of us the deteriorating social environment for smoking made it easier to quit.

Implementing this sort of intervention is beyond the scope of one research investigator or even a consortium of researchers collaborating across many sites. It requires the cooperation of governmental, educational, and even religious institutions. We may need to rethink our approach to preventing drug use and abuse. (Cook, 1993, p. 1750)

## Concept Check | 11.4

Determine whether you understand how treatments for substance-related disorders work by matching the examples with the following terms: (a) dependent, (b) cross-tolerant, (c) agonist substitution, (d) antagonist, (e) relapse prevention, (f) controlled drinking, (g) aversion therapy, (h) covert sensitization, (i) contingency management, and (j) anonymous.

1. ______________ is a controversial treatment for alcohol abuse because of a negative but flawed experimental finding, but also because it conflicts with the belief in total abstinence.
2. Methadone is used to help heroin addicts kick their habit in a method called ______________.
3. ______________ drugs block or counteract the effects of psychoactive drugs and are sometimes effective in treating addicts.
4. In ______________, the clinician and the client work together to decide which behaviors the client needs to change and which reinforcers will be used as rewards for reaching set goals.
5. It has been difficult to evaluate rigorously the effectiveness of Alcoholics Anonymous because the participants are ______________.
6. In ______________, substance use is paired with something extremely unpleasant (like alcohol and vomiting with Antabuse).
7. Heroin and methadone are ______________, which means they affect the same neurotransmitter receptors.
8. The ______________ model involves therapy that helps individuals remove ambivalence about stopping their drug use by examining their beliefs about the positive and negative aspects of drug use.
9. By imagining unpleasant scenes, the ______________ technique helps the person associate the negative effects of the drug with drug use.
10. Unfortunately, the heroin addict may become permanently ______________ on methadone.

# Impulse-Control Disorders

A number of the disorders we describe in this book start with an irresistible impulse—usually one that will ultimately be harmful to the person affected. Typically, the person experiences increasing tension leading up to the act and, sometimes, pleasurable anticipation of acting on the impulse. For example, paraphilias such as pedophilia (sexual attraction to children), eating disorders, and the substance-related disorders in this chapter often commence with temptations or desires that are destructive but difficult to resist. *DSM-IV-TR* includes five additional impulse-control disorders (labeled "impulse-control disorders not elsewhere classified") that are not included under other categories—intermittent explosive disorder, kleptomania, pyromania, pathological gambling, and trichotillomania (Moeller, 2009; Nock, Cha, & Dour, in press).

## Intermittent Explosive Disorder

People with **intermittent explosive disorder** have episodes in which they act on aggressive impulses that result in serious assaults or destruction of property (Coccaro & McCloskey, 2010). Although it is unfortunately common among the general population to observe aggressive outbursts, when you rule out the influence of other disorders (for example, antisocial personality disorder, borderline personality disorder, a psychotic disorder, and Alzheimer's disease) or substance use, this disorder is not often diagnosed. In a rare but important large study of more than 9,000 people, researchers found that the lifetime prevalence of this disorder was 7.3% (Kessler et al., 2006).

This diagnosis is controversial and has been debated throughout the development of the *DSM*. One concern, among others, is that by validating a general category that covers aggressive behavior it may be used as a legal defense—insanity—for all violent crimes (Coccaro & McCloskey, 2010).

Research is at the beginning stages for intermittent explosive disorder and focuses on the influence of neurotransmitters such as serotonin and norepinephrine and testosterone levels, along with their interaction with psychosocial influences (stress, disrupted family life, and parenting styles). These and other influences are being examined to explain the origins of this disorder (Moeller, 2009). Cognitive-behavioral interventions (for example, helping the person identify and avoid "triggers" for aggressive outbursts) and approaches modeled after drug treatments appear the most effective for these individuals, although few controlled studies yet exist (McCloskey, Noblett, Deffenbacher, Gollan, & Coccaro, 2008).

## Kleptomania

The story of wealthy actress Winona Ryder stealing $5,500 worth of merchandise from Saks Fifth Avenue in Beverly Hills, California, in December 2001, was as puzzling as it was titillating. Why risk a multimillion-dollar career over some clothes that she could easily afford? Was hers a case of **kleptomania**—a recurrent failure to resist urges to steal things that are not needed for personal use or their monetary value? This disorder appears to be rare, but it is not well studied, partly because of the stigma associated with identifying oneself as acting out this illegal behavior. The patterns described by those with this disorder are strikingly similar—the person begins to feel a sense of tension just before stealing, which is followed by feelings of pleasure or relief while the theft is committed (Nock et al., in press). People with kleptomania score high on assessments of impulsivity, reflecting their inability to judge the immediate gratification of stealing compared to the long-term negative consequences (for example, arrest, embarrassment) (Grant & Kim, 2002). Patients with kleptomania often report having no memory (amnesia) about the act of shoplifting (Hollander, Berlin, & Stein, 2009). Brain-imaging research supports these observations, with one study finding damage in areas of the brain associated with poor decision making (inferior frontal regions) (Grant, Correia, & Brennan-Krohn, 2006).

©Landov Media

▲ In 2002, actress Winona Ryder was found guilty of shoplifting items worth several thousand dollars from a Beverly Hills department store.

There appears to be high comorbidity between kleptomania and mood disorders, and to a lesser extent with substance abuse and dependence (Baylé, Caci, Millet, Richa, & Olié, 2003). Some refer to kleptomania as an "antidepressant" behavior, or a reaction on the part of some to relieve unpleasant feelings through stealing (Fishbain, 1987). To date, only case study reports of treatment exist, and these involve either behavioral interventions or use of antidepressant medication.

## Pyromania

Just as we know that someone who steals does not necessarily have kleptomania, it is also true that not everyone who sets fires is considered to have **pyromania**—an impulse-control disorder that involves having an irresistible urge to set fires. Again, the pattern parallels that of kleptomania, where the person feels a tension or arousal before setting a fire and a sense of gratification or relief while the fire burns. These individuals will also be preoccupied with fires and the associated equipment involved in setting and putting out these fires (Lejoyeux, McLoughlin, & Ades, 2006). Also rare, pyromania is diagnosed in less than 4% of arsonists (Scott, Hilty, & Brook, 2003), because arsonists can include people who set fires for monetary gain or revenge rather than to satisfy a physical or psychological urge. Because so few people are diagnosed with this disorder, research on etiology and treatment is almost nonexistent. Research that has been conducted follows the general group of arsonists (of which only a small percentage have pyromania) and examines the role of a family history of fire setting along with comorbid impulse disorders (antisocial personality disorder and alcoholism). Treatment is generally cognitive-behavioral and involves helping the person identify the signals that initiate the urges and teaching coping strategies to resist the temptation to start fires (Bumpass, Fagelman, & Brix, 1983; McGrath, Marshall, & Prior, 1979).

## Pathological Gambling

Gambling has a long history—for example, dice have been found in Egyptian tombs (Greenberg, 2005). It is growing in popularity in this country, and in many places it is a legal and acceptable form of entertainment. Perhaps as a result, and unlike the other impulse-control disorders, which are relatively rare, **pathological gambling** affects an increasing number of people, estimated between 3% and 5% of adult Americans (Greenberg, 2005). It is estimated that among pathological gamblers, 14% have lost at least one job, 19% have declared bankruptcy, 32% have been arrested, and 21% have been incarcerated (Gerstein et al., 1999). The *DSM-IV-TR* criteria for pathological gambling set forth the associated behaviors that characterize people who are problem gamblers. These include the same pattern of urges we observe in the other impulse-control disorders. Note too the parallels with substance dependence, with the need to gamble increasing amounts of money over time and the "withdrawal symptoms" such as restlessness and irritability when attempting to stop. In fact, these parallels to substance abuse have led to discussions about recategorizing pathological gambling in *DSM-5;* some believe that this disorder should be moved from the group of disorders called "impulse-control disorders not elsewhere classified" to the "substance-related disorders" category and that this "substance-related disorders" category should be renamed "addiction and related disorders" (Moeller, 2009).

There is a growing body of research on the nature and treatment of pathological gambling. For example, work is under way to explore the biological origins of the urge to gamble among pathological gamblers. In one study, brain-imaging technology (echoplanar functional magnetic resonance imaging) was used to observe brain function while gamblers observed videotapes of other people gambling (Potenza et al., 2003). A decreased level of activity was observed in those regions of the brain that are involved in impulse regulation when compared to controls, suggesting an interaction between the environmental cues to gamble and the brain's response (which may be to decrease the ability to resist these cues). Abnormalities in the dopamine system (which may account for the pleasurable consequences of gambling) and the serotonin system (involved in impulsive behavior) have been found in some studies of pathological gamblers (Moeller, 2009).

Treatment of gambling problems is difficult. Those with pathological gambling exhibit a combination of characteristics—including denial of the problem, impulsivity, and continuing optimism ("One big win will cover my losses!")—that interfere with effective treatment. Pathological gamblers often experience cravings similar to those who are substance dependent (Wulfert, Franco, Williams, Roland, & Maxson, 2008; Wulfert, Maxson, & Jardin, 2009). Treatment is often similar to substance dependence treatment, and there is a parallel Gambler's Anonymous that incorporates the same 12-step program we discussed previously. However, the evidence of effectiveness for Gambler's Anonymous suggests that 70% to 90% drop out of these programs and that the desire to quit must be present before intervention (McElroy & Arnold, 2001). Cognitive-behavioral interventions are also being studied, with one study including a variety of components—setting financial limits, planning alternative activities, preventing relapse, and imaginal desensitization. This preliminary research provides a more optimistic view of potential outcomes (Dowling, Smith, & Thomas, in press).

**DSM-IV-TR** **Table 11.13** Diagnostic Criteria for Pathological Gambling

**A.** Persistent and recurrent maladaptive gambling behavior as indicated by five (or more) of the following:
   **1.** Is preoccupied with gambling (e.g., preoccupied with reliving past gambling experiences, handicapping or planning the next venture, or thinking of ways to get money with which to gamble)
   **2.** Needs to gamble with increasing amounts of money in order to achieve the desired excitement
   **3.** Has repeated unsuccessful efforts to control, cut back, or stop gambling
   **4.** Is restless or irritable when attempting to cut down or stop gambling
   **5.** Gambles as a way of escaping from problems or of relieving dysphoric mood (e.g., feelings of helplessness, guilt, anxiety, depression)
   **6.** After losing money gambling, often returns another day to get even ("chasing" one's losses)
   **7.** Lies to family members, therapist, or others to conceal the extent of involvement with gambling
   **8.** Has committed illegal acts such as forgery, fraud, theft, or embezzlement to finance gambling
   **9.** Has jeopardized or lost a significant relationship, job, or educational or career opportunity because of gambling
   **10.** Relies on others to provide money to relieve a desperate financial situation caused by gambling

**B.** The gambling behavior is not better accounted for by a manic episode.

## Trichotillomania

The urge to pull out one's own hair from anywhere on the body, including the scalp, eyebrows, and arms, is referred to as **trichotillomania**. This behavior results in noticeable hair loss, distress, and significant social impairments. This disorder can often have severe social consequences, and, as a result, those affected can go to great lengths to conceal their behavior. Compulsive hair pulling is more common than once believed and is observed in between 1% and 5% of college students, with females reporting the problem more than males (Scott et al., 2003). There may be some genetic influence on trichotillomania, with one study finding a unique genetic mutation in a small number of people (Zuchner et al., 2006). Stress also seems to be involved, and there is an increased overlap with posttraumatic stress disorder (Chamberlain, Menzies, Sahakian, & Fineberg, 2007). There is considerable controversy over just how this problem should be classified, and there is a proposal to reclassify it from "impulse control disorders not elsewhere classified" to "anxiety and obsessive-compulsive spectrum disorders" in *DSM-5* (Nock et al., in press). Research using serotonin-specific reuptake inhibitors holds some promise for treatment, as do cognitive-behavioral interventions, although rigorous research trials have yet to be conducted (Chamberlain et al., 2007).

In addition to these five impulse-control disorders, other impulsive behaviors may occasionally rise to the level of these difficulties. Some individuals show the same irresistible urges to engage in compulsive buying or shopping (oniomania), self-mutilation, skin picking (psychogenic excoriation), severe nail biting (onychophagia), and excessive computer use ("Internet addiction") (McElroy & Arnold, 2001). There is a limited but growing literature that will help us understand and ultimately treat these impulse-control problems.

## Concept Check 11.5

Match the following disorders with their corresponding symptoms: (a) pathological gambling, (b) trichotillomania, (c) intermittent explosive disorder, (d) kleptomania, and (e) pyromania.

1. This rarely diagnosed disorder is characterized by episodes of aggressive impulses and can sometimes be treated with cognitive-behavioral interventions, drug treatments, or both. ______________
2. This disorder begins with the person feeling a sense of tension that is released and followed with pleasure after they have committed a robbery. ______________
3. This disorder affects somewhere between 3% and 5% of the adult American population and is characterized by the need to gamble. ______________
4. This disorder refers to compulsive hair pulling and is more common in females than males. ______________
5. Individuals with this disorder are preoccupied with fires and the equipment involved in setting and putting out fires. ______________

## On the Spectrum

### Emerging Views of Substance-Related Disorders

Research on a spectrum of disorders that covers the substance-related disorders or the impulse-control disorders is in its infancy. One of the difficulties in researching these disorders is their complexity. The problems that fall under disorders of substance use or impulse control are multifaceted and overlap a great deal with other disorders (comorbidity). For example, people with disorders as wide ranging as antisocial personality disorder (see Chapter 12) (Copeland, Shanahan, Costello, & Angold, 2009), anxiety disorders (see Chapter 5) (Hofmann, Richey, Kashdan, & McKnight, 2009), schizophrenia (see Chapter 13) (Horsfall, Cleary, Hunt, & Walter, 2009), bipolar disorder (see Chapter 7) (Joshi & Wilens, 2009), and depression (see Chapter 7) (Rao, Hammen, & Poland, 2009) all have an increased risk of also meeting criteria for a substance-related disorder. At the same time, there are other mental health concerns that resemble the pattern of use, dependence, and withdrawal of the substance-related disorders but do not involve the use of mood-altering substances. For example, as we have seen, discussion is under way to include pathological gambling as part of a new category of disorders, "addiction and related disorders," in *DSM-5*—which would then expand the "addictions" beyond just mood-altering substances (Moeller, 2009). Other problems that cause real dysfunction among some people, including "Internet addiction" (Block, 2008) and even "tanning addiction" (Poorsattar & Hornung, 2010), are being taken seriously as similar types of problems.

One contender for a spectrum of disorders that is currently being researched is referred to as the *externalizing spectrum* (Krueger, Markon, Patrick, & Iacono, 2005; Sher et al., in press). This categorization includes the substance-related disorders along with antisocial behavior (a personality disorder characterized by the violation of social norms with a disregard for the rights and feelings of others; see Chapter 12) and personality traits such as aggression and impulsivity, all of which often occur together (Krueger et al., 2005). If we return to the case of Danny, we can see that he displayed many if not all of the characteristics of this spectrum of disorders. Recall that in addition to his substance abuse problems he would steal from his family and his employers, he lied frequently to everyone, and yet he never expressed any true remorse for how his behavior impacted others—all characteristics of antisocial personality disorder. In fact, even awaiting trial in jail for his DWI-related traffic fatality, he was talking to as many people as he could to try to blame the medication he was on at the time for his difficulty and never admitted any guilt or expressed any concern for the family of the woman he killed. This collection of difficulties, which have at their core a variety of characteristics including novelty seeking and sensation seeking, is now being explored in a variety of research paradigms (including genetic research) as a possible unifying spectrum that may lead to a deeper understanding of these troubling problems (e.g., Dick et al., 2008).

# Summary

### Perspectives on Substance-Related Disorders

- In *DSM-IV-TR,* substance-related disorders are divided into depressants (alcohol, barbiturates, and benzodiazepines), stimulants (amphetamine, cocaine, nicotine, and caffeine), opiates (heroin, codeine, and morphine), and hallucinogens (marijuana and LSD).
- Specific diagnoses are further categorized as substance dependence, substance abuse, substance intoxication, and substance withdrawal.
- Nonmedical drug use in the United States has declined in recent times, although it continues to cost billions of dollars and seriously impairs the lives of millions of people each year.

### Depressants, Stimulants, Opioids, and Hallucinogens

- Depressants are a group of drugs that decrease central nervous system activity. The primary effect is to reduce our levels of physiological arousal and help us relax. Included in this group are alcohol and sedative, hypnotic, and anxiolytic drugs, such as those prescribed for insomnia.
- Stimulants, the most commonly consumed psychoactive drugs, include caffeine (in coffee, chocolate, and many soft drinks), nicotine (in tobacco products such as cigarettes), amphetamines, and cocaine. In contrast to the depressant drugs, stimulants make us more alert and energetic.
- Opiates include opium, morphine, codeine, and heroin; they have a narcotic effect—relieving pain and inducing sleep. The broader term *opioids* is used to refer to the family of substances that includes these opiates and synthetic variations created by chemists (e.g., methadone) and the similarly acting substances that occur naturally in our brains (enkephalins, beta-endorphins, and dynorphins).
- Hallucinogens essentially change the way the user perceives the world. Sight, sound, feelings, and even smell are distorted, sometimes in dramatic ways, in a person under the influence of drugs such as marijuana and LSD.

### Causes and Treatment of Substance-Related Disorders

- Most psychotropic drugs seem to produce positive effects by acting directly or indirectly on the dopaminergic mesolimbic system (the pleasure pathway). In addition, psychosocial factors such as expectations, stress, and cultural practices interact with the biological factors to influence drug use.
- Substance dependence is treated successfully only in a minority of those affected, and the best results reflect the motivation of the drug user and a combination of biological and psychosocial treatments.
- Programs aimed at preventing drug use may have the greatest chance of significantly affecting the drug problem.

### Impulse-Control Disorders

- In *DSM-IV-TR,* impulse-control disorders include five separate disorders: intermittent explosive disorder, kleptomania, pyromania, pathological gambling, and trichotillomania.

# Key Terms

**substance-related disorders, 391**
**impulse-control disorders, 391**
**polysubstance use, 391**
**psychoactive substance, 392**
**substance intoxication, 393**
**substance abuse, 393**
**substance dependence, 394**
**tolerance, 394**
**withdrawal, 394**
**depressants, 396**
**stimulants, 396**
**opiates, 396**
**hallucinogens, 396**
**alcohol use disorders, 396**
**withdrawal delirium (delirium tremens/DTs), 398**
**fetal alcohol syndrome (FAS), 398**
**alcohol dehydrogenase (ADH), 399**
**barbiturates, 401**
**benzodiazepines, 401**
**amphetamine use disorders, 402**
**cocaine use disorders, 403**
**nicotine use disorders, 405**
**caffeine use disorders, 407**
**opioid use disorders, 407**
**hallucinogen use disorders, 408**
**marijuana (*Cannabis sativa*), 408**
**LSD (*d*-lysergic acid diethylamide), 410**
**agonist substitution, 420**
**antagonist drug, 420**
**controlled drinking, 421**
**relapse prevention, 422**
**intermittent explosive disorder, 424**

## Answers to Concept Checks

### 11.1

*Part A*

**1.** c; **2.** b; **3.** d; **4.** a

*Part B*

**5.** c; **6.** d; **7.** b; **8.** a

### 11.2

**1.** False (the use of crack by pregnant mothers adversely affects only some babies); **2.** True; **3.** True; **4.** False (marijuana produces the most variable reactions in people); **5.** False (amphetamines are produced in the lab); **6.** True; **7.** False (stimulants occur naturally)

### 11.3

*Part A*

**1.** f; **2.** c; **3.** d; **4.** a; **5.** e; **6.** b

*Part B*

**7.** T; **8.** T; **9.** F (all have an effect); **10.** F (they would still act uninhibited); **11.** T

### 11.4

**1.** f; **2.** c; **3.** d; **4.** i; **5.** j; **6.** g; **7.** b; **8.** e; **9.** h; **10.** a

### 11.5

**1.** c; **2.** d; **3.** a; **4.** b; **5.** e

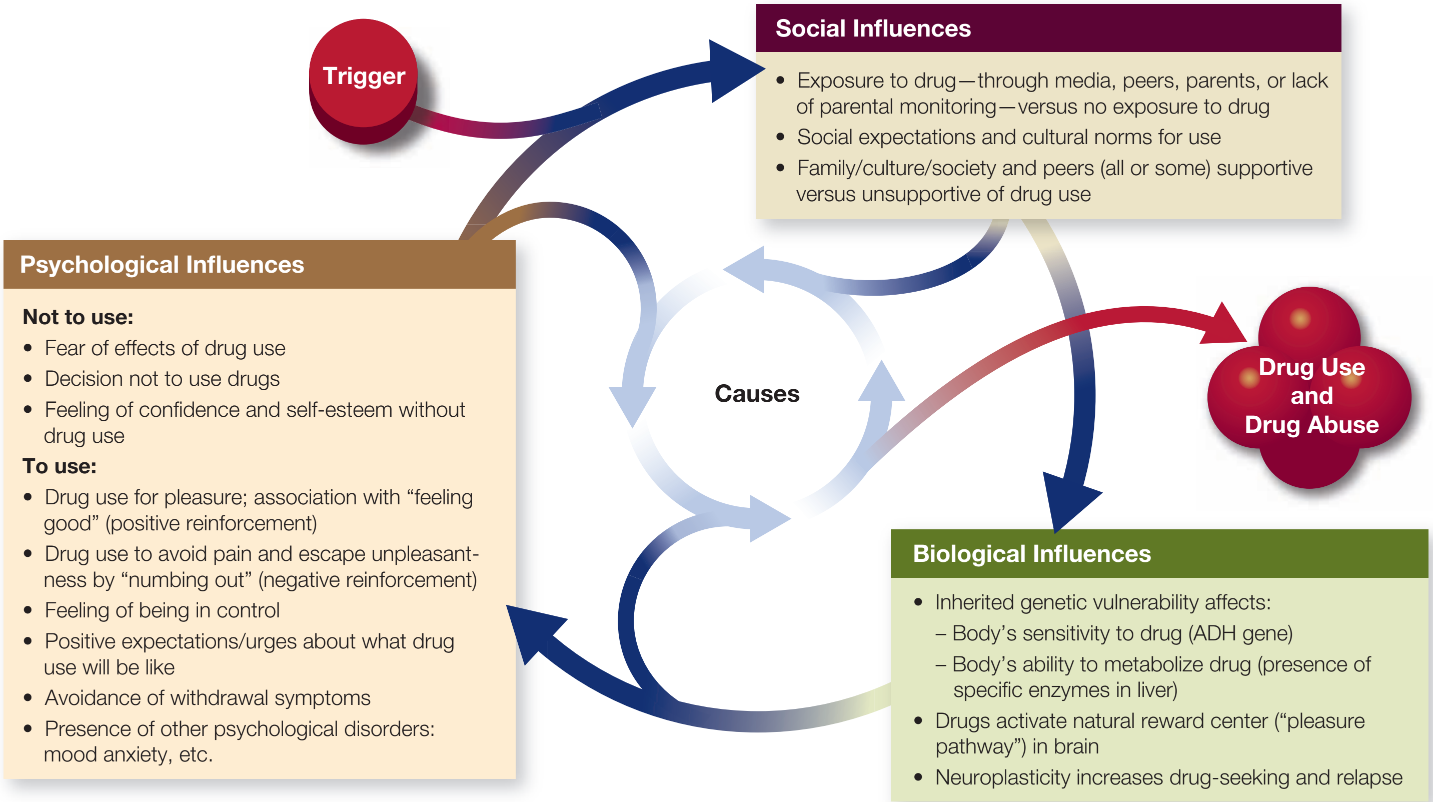
- Designer Drugs
- Drug Use: Psychological Perspective
- Concept Check: Impulse Control Disorders Versus Substance Use

# Exploring Substance-Related Disorders

- Many kinds of problems can develop when people use and abuse substances that alter the way they think, feel, and behave.
- Once seen as due to personal weakness, drug abuse and dependence are now thought influenced by both biological and psychosocial factors.



### Social Influences

- Exposure to drug—through media, peers, parents, or lack of parental monitoring—versus no exposure to drug
- Social expectations and cultural norms for use
- Family/culture/society and peers (all or some) supportive versus unsupportive of drug use

### Psychological Influences

**Not to use:**

- Fear of effects of drug use
- Decision not to use drugs
- Feeling of confidence and self-esteem without drug use

**To use:**

- Drug use for pleasure; association with "feeling good" (positive reinforcement)
- Drug use to avoid pain and escape unpleasantness by "numbing out" (negative reinforcement)
- Feeling of being in control
- Positive expectations/urges about what drug use will be like
- Avoidance of withdrawal symptoms
- Presence of other psychological disorders: mood anxiety, etc.

### Biological Influences

- Inherited genetic vulnerability affects:
  - Body's sensitivity to drug (ADH gene)
  - Body's ability to metabolize drug (presence of specific enzymes in liver)
- Drugs activate natural reward center ("pleasure pathway") in brain
- Neuroplasticity increases drug-seeking and relapse

## TREATMENT: BEST TO USE MULTIPLE APPROACHES

### Psychosocial Treatments

- Aversion therapy—to create negative associations with drug use (shocks with drinking, imagining nausea with cocaine use)
- Contingency management to change behaviors by rewarding chosen behaviors
- Alcoholics Anonymous and its variations
- Inpatient hospital treatment (can be expensive)
- Controlled use
- Community reinforcement
- Relapse prevention

### Biological Treatments

- Agonist substitution
  - Replacing one drug with a similar one (methadone for heroin, nicotine gum and patches for cigarettes)
- Antagonist substitution
  - Blocking one drug's effect with another drug (naltrexone for opiates and alcohol)
- Aversive treatments
  - Making taking drug very unpleasant (using Antabuse, which causes nausea and vomiting when mixed with alcohol, to treat alcoholism)
- Drugs to help recovering person deal with withdrawal symptoms (clonidine for opiate withdrawal, sedatives for alcohol, etc.)

## TYPES OF DRUGS

| | Examples | Effects |
|---|---|---|
| Depressants | Alcohol, barbiturates (sedatives: Amytal, Seconal, Nembutal), benzodiazepines (antianxiety: Valium, Xanax, Halcion) | • Decreased central nervous system activity<br>• Reduced levels of body arousal<br>• Relaxation |
| Stimulants | Amphetamines, cocaine, nicotine, caffeine | • Increased physical arousal<br>• User feels more alert and energetic |
| Opiates | Heroin, morphine, codeine | • Narcotic—reduce pain and induce sleep and euphoria by mirroring opiates in the brain (endorphins, etc.) |
| Hallucinogens | Marijuana, LSD, Ecstasy | • Altered mental and emotional perception<br>• Distortion (sometimes dramatic) of sensory perceptions |

# Exploring Impulse-Control Disorders

Characterized by inability to resist acting on a drive or temptation. Sufferers often perceived by society as having a problem simply due to a lack of "will."

## TYPES OF IMPULSE-CONTROL DISORDERS

| Disorder | | Characteristics | Treatment |
|---|---|---|---|
| **Intermittent Explosive** | Tom Morrison/Getty Images | • Acting on aggressive impulses that result in assaults or destruction of property<br>• Current research is focused on how neurotransmitters and testosterone levels interact with psychosocial influences (stress, parenting styles) | Cognitive-behavioral interventions (helping person identify and avoid triggers for aggressive outbursts) and approaches modeled after drug treatments appear most effective |
| **Kleptomania** | Mauro Speziale/Getty Images | • Recurring failure to resist urges to steal unneeded items<br>• Feeling tense just before stealing, followed by feelings of pleasure or relief when committing the theft<br>• High comorbidity with mood disorders and, to a lesser degree, with substance abuse/dependence | Behavioral interventions or antidepressant medication |
| **Pathological Gambling** | Tom and Steve/Getty Images | • Preoccupation with gambling/with need to gamble increasing amounts of money to feel the same excitement<br>• "Withdrawal symptoms" of restlessness and irritability when attempting to stop<br>• May have a biological component involving brain activity (decreased activity in brain region controlling impulse regulation, abnormalities in dopamine and serotonin systems) | Gamblers Anonymous; similar to substance-dependence treatment |
| **Trichotillomania** | ©Wedgworth/Custom Medical Stock Photo (CMSP) | • Urge to pull out one's own hair from anywhere on the body<br>• Sufferers go to great lengths to conceal behavior<br>• Relatively common (seen 1%–5% of college students) | SSRIs may help; cognitive-behavior interventions hold promise |
| **Pyromania** | Joel Sartore/Getty Images | • Irresistible urge to set fires<br>• Feeling aroused prior to setting fire then a sense of gratification or relief while the fire burns<br>• Rare; diagnosed in less than 4% of arsonists | Cognitive-behavioral interventions (helping person identify signals triggering urges, and teaching coping strategies to resist setting fires) |

## STUDENT LEARNING OUTCOMES*

| | |
|---|---|
| **Demonstrate knowledge and understanding representing appropriate breadth and depth in selected content areas of psychology:** | › Biological bases of behavior and mental processes, including physiology, sensation, perception, comparative, motivation, and emotion (APA SLO 1.2.a (3)) ***(see textbook pages 448–450)*** |
| **Use the concepts, language, and major theories of the discipline to account for psychological phenomena.** | › Describe behavior and mental processes empirically, including operational definitions (APA SLO 1.3.a) ***(see textbook pages 433–462)*** |
| **Identify appropriate applications of psychology in solving problems, such as:** | › Origin and treatment of abnormal behavior (APA SLO 4.2.b) ***(see textbook pages 440–445, 451–455, 457–462)*** |

---

* Portions of this chapter cover learning outcomes suggested by the American Psychological Association (2007) in their guidelines for the undergraduate psychology major. Chapter coverage of these outcomes is identified above by APA Goal and APA Suggested Learning Outcome (SLO).

# An Overview of Personality Disorders

According to the fourth edition, text revision, of the *Diagnostic and Statistical Manual (DSM-IV-TR),* **personality disorders** are "enduring patterns of perceiving, relating to, and thinking about the environment and oneself that are exhibited in a wide range of social and personal contexts," and "are inflexible and maladaptive, and cause significant functional impairment or subjective distress" (American Psychiatric Association, 2000, p. 686). Now that you have taken out your yellow marker and highlighted this definition of personality disorders, what do you think it means?

We all think we know what a personality is. It's all the characteristic ways a person behaves and thinks: "Michael tends to be shy"; "Mindy likes to be dramatic"; "Juan is always suspicious of others"; "Annette is outgoing"; "Bruce seems to be sensitive and gets upset easily over minor things"; "Sean has the personality of an eggplant!" We tend to type people as behaving in one way in many situations. For example, like Michael, many of us are shy with people we don't know, but we won't be shy around our friends. A truly shy person is shy even among people he has known for some time. The shyness is part of the way the person behaves in most situations. We also have all probably behaved in all the other ways noted here (dramatic, suspicious, outgoing, easily upset). However, we usually consider a way of behaving part of a person's personality only if it occurs in many times and places. In this chapter, we look at characteristic ways of behaving in relation to personality disorders. First we examine how we conceptualize personality disorders and the issues related to them; then we describe the disorders themselves.

## Aspects of Personality Disorders

What if a person's characteristic ways of thinking and behaving cause significant distress to the self or others? What if the person can't change this way of relating to the world and is unhappy? We might consider this person to have a personality disorder. The *DSM-IV-TR* definition notes that these personality characteristics are "inflexible and maladaptive and cause significant functional impairment or subjective distress." Unlike many of the disorders we have already discussed, personality disorders are chronic; they do not come and go but originate in childhood and continue throughout adulthood. Because they affect personality, these chronic problems pervade every aspect of a person's life. For example, if a woman is overly suspicious (a sign of a possible paranoid personality disorder), this trait will affect almost everything she does, including her employment (she may have to change jobs often if she believes coworkers conspire against her), her relationships (she may not be able to sustain a lasting relationship if she can't trust anyone), and even where she lives (she may have to move often if she suspects her landlord is out to get her).

*DSM-IV-TR* notes that having a personality disorder may distress the affected person. However, individuals with personality disorders may not feel any subjective distress; indeed, it may be others who acutely feel distress because of the actions of the person with the disorder. This is particularly common with antisocial personality disorder, because the individual may show a blatant disregard for the rights of others yet exhibit no remorse (Patrick, 2006). In certain cases, someone other than the person with the personality disorder must decide whether the disorder is causing significant functional impairment, because the affected person often cannot make such a judgment.

*DSM-IV-TR* lists 10 specific personality disorders and several others that are being studied for future consideration; we review them all. Although the prospects for treatment success for people who have personality disorders may be more optimistic than previously thought (see, for example, Svartberg, Stiles, & Seltzer, 2004), unfortunately, as you will see later, many people who have personality disorders in addition to other psychological problems (for example, major depression) tend to do poorly in treatment. One factor important to the success (or lack of success) of treatment is how the therapist feels about the client. The emotions of therapists brought out by clients (called "countertransference" by Sigmund Freud) tend to be negative for those diagnosed with personality disorders, especially those (as you will see next) in Cluster A (the odd or eccentric cluster) and Cluster B (the dramatic, emotional, or erratic cluster) (Rossberg, Karterud, Pedersen, & Friis, 2007). Therapists especially need to guard against letting their personal feelings interfere with treatment when working with people who have personality disorders.

Most disorders we discuss in this book are in Axis I of the *DSM-IV-TR,* which includes the standard traditional disorders. The personality disorders are included in a separate axis, Axis II, because as a group they are distinct. The characteristic traits are more ingrained and inflexible in people who have personality disorders, and the disorders themselves are less likely to be successfully modified.

Because personality disorders are on a separate axis, clinicians are required to consider symptom by symptom whether the person has a personality disorder. In the axis system, a patient can receive a diagnosis on only Axis I, only Axis II, or on both axes. A diagnosis on both Axis I and Axis II indicates that a person has both a current disorder (Axis I) and a more chronic problem (for example, personality disorder). As you will see, it is not unusual for one person to be diagnosed on both axes.

You may be surprised to learn that the category of personality disorders is controversial, because it involves a number of unresolved issues. Examining these issues can help you understand all the disorders described in this book.

## Categorical and Dimensional Models

Most of us are sometimes suspicious of others and a little paranoid, overly dramatic, too self-involved, or reclusive. Fortunately, these characteristics have not lasted long or been overly intense, and they haven't significantly impaired how we live and work. People with personality disorders, however, display problem characteristics over extended periods and in many situations, which can cause great emotional pain for themselves, others, or both (Ferguson, 2010b). Their difficulty, then, can be seen as one of *degree* rather than *kind;* in other words, the problems of people with personality disorders may just be extreme versions of the problems many of us experience temporarily, such as being shy or suspicious (South, Oltmanns, & Krueger, in press).

The distinction between problems of degree and problems of kind is usually described in terms of *dimensions* instead of *categories.* The issue that continues to be debated in the field is whether personality disorders are extreme versions of otherwise normal personality variations (dimensions) or ways of relating that are different from psychologically healthy behavior (categories) (Widiger & Trull, 2007). You can see the difference between dimensions and categories in everyday life. For example, we tend to look at gender categorically. Our society views us as being in one category—"female"—or the other—"male." Yet we could also look at gender in terms of dimensions. For example, we know that "maleness" and "femaleness" are partly determined by hormones. We could identify people along testosterone, estrogen, or both dimensions and rate them on a continuum of maleness and femaleness rather than in the absolute categories of male or female. We also often label people's size categorically, as tall, average, or short. But height, too, can be viewed dimensionally, in inches or centimeters.

Many researchers and clinicians in this field see personality disorders as extremes on one or more personality dimensions. Yet because of the way people are diagnosed with the *DSM,* the personality disorders—like most other disorders—end up being viewed in categories. You have two choices—either you do ("yes") or you do not ("no") have a disorder. For example, either you have antisocial personality disorder or you don't. The *DSM* doesn't rate how dependent you are; if you meet the criteria, you are labeled as having dependent personality disorder. There is no "somewhat" when it comes to personality disorders.

There are advantages to using categorical models of behavior, the most important being their convenience. With simplification, however, come problems. One is that the mere act of using categories leads clinicians to reify them; that is, to view disorders as real "things," comparable to the realness of an infection or a broken arm. Some argue that personality disorders are not things that exist but points at which society decides a particular way of relating to the world has become a problem. There is the important unresolved issue again: Are personality disorders just an extreme variant of normal personality, or are they distinctly different disorders?

Some have proposed that the *DSM-IV-TR* personality disorders section be replaced or at least supplemented by a dimensional model (South et al., in press; Widiger & Trull, 2007) in which individuals would not only be given categorical diagnoses but also would be rated on a series of personality dimensions. Widiger (1991) believes such a system would have at least three advantages over a purely categorical system: (1) It would retain more information about each individual, (2) it would be more flexible because it would permit both categorical and dimensional differentiations among individuals, and (3) it would avoid the often arbitrary decisions involved in assigning a person to a diagnostic category.

Although no general consensus exists about what the basic personality dimensions might be, there are several contenders (South et al., in press). One of the more widely accepted is called the *five-factor model,* or the "Big Five," and is taken from work on normal personality (McCrae & Costa Jr., 2008). In this model, people can be rated on a series of personality dimensions, and the combination of five components describes why people are so different. The five factors or dimensions are *extroversion* (talkative, assertive, and active versus silent, passive, and reserved); *agreeableness* (kind, trusting, and warm versus hostile, selfish, and mistrustful); *conscientiousness* (organized, thorough, and reliable versus careless, negligent, and unreliable); *neuroticism* (even-tempered versus nervous, moody, and temperamental); and *openness to experience* (imaginative, curious, and creative versus shallow and imperceptive) (McCrae & Costa Jr., 2008). On each dimension, people are rated high, low, or somewhere between.

Cross-cultural research establishes the universal nature of the five dimensions—although there are individual differences across cultures (Hofstede & McCrae, 2004). For example, one study found in general that Austrian, Swiss, and Dutch samples scored the highest on openness to experience, whereas the Danes, Malaysians, and Telugu Indians (India) scored the lowest on this factor (McCrae, 2002). A number of researchers are trying to determine whether people with personality disorders can also be rated in a meaningful way along these dimensions and whether the system will help us better understand these disorders (Skodol et al., 2005).

An alternative model that derives from clinical work with people who have personality disorders is proposed by Westen and Shedler (2004). Their model identifies twelve personality dimensions (as opposed to the five in the five-factor model) that not only overlap with *DSM* criteria but also introduce new aspects of personality not previously tapped in the *DSM* (see Table 12.1). In addition to Westen and Shedler's model, there are over a dozen other dimensional systems of classifying personality disorders having varying levels of support, but as yet no one approach dominates the field (South et al., in press).

Again, an obstacle to the adoption of a dimensional approach to personality disorders is the lack of consensus regarding the most appropriate framework. However, there is a growing consensus

**TABLE 12.1** Two Dimensional Models of Personality

| Dimension | Description |
|---|---|
| **Five-Factor Model** | |
| Neuroticism | Proneness to psychological distress and impulsive behavior |
| Extroversion | Tendency to join in social situations and feel joy and optimism |
| Openness to experience | Curiosity, receptivity to new ideas, and emotional expressiveness |
| Agreeableness | Extent to which someone shows both compassion and hostility toward others |
| Conscientiousness | Degree of organization and commitment to personal goals |
| **Westen and Shedler Model** | |
| Psychological health | Ability to love others, find meaning in life, and gain personal insights |
| Psychopathy | Lack of remorse, presence of impulsiveness, and tendency to abuse drugs |
| Hostility | Deep-seated ill will |
| Narcissism | Self-importance, grandiose assumptions about oneself, and tendency to treat others as an audience to provide admiration |
| Emotional dysregulation | Intense and uncontrolled emotional reactions |
| Dysphoria | Depression, shame, humiliation, and lack of any pleasurable experiences |
| Schizoid orientation | Constricted emotions, inability to understand abstract concepts such as metaphors, and few or no friends |
| Obsessionality | Absorption in details, stinginess, and fear of dirt and contamination |
| Thought disorder | Such as believing one has magical powers over others or can directly read their minds |
| Oedipal conflict | Adult pursuit of romantic partners who are already involved with others, inappropriate seductiveness, and intense sexual jealousy |
| Dissociated consciousness | Fragmenting of thought and perception often related to past sexual abuse |
| Sexual conflict | Anxieties and fears regarding sexual intimacy |

**DSM-IV-TR** **Table 12.1** Personality Disorders

| Personality Disorder | Description |
|---|---|
| **Cluster A—Odd or Eccentric Disorders** | |
| Paranoid personality disorder | A pervasive distrust and suspiciousness of others such that their motives are interpreted as malevolent. |
| Schizoid personality disorder | A pervasive pattern of detachment from social relationships and a restricted range of expression of emotions in interpersonal settings. |
| Schizotypal personality disorder | A pervasive pattern of social and interpersonal deficits marked by acute discomfort with reduced capacity for close relationships, as well as by cognitive or perceptual distortions and eccentricities of behavior. |
| **Cluster B—Dramatic, Emotional, or Erratic Disorders** | |
| Antisocial personality disorder | A pervasive pattern of disregard for and violation of the rights of others. |
| Borderline personality disorder | A pervasive pattern of instability of interpersonal relationships, self-image, affects, and control over impulses. |
| Histrionic personality disorder | A pervasive pattern of excessive emotion and attention seeking. |
| Narcissistic personality disorder | A pervasive pattern of grandiosity (in fantasy or behavior), need for admiration, and lack of empathy. |
| **Cluster C—Anxious or Fearful Disorders** | |
| Avoidant personality disorder | A pervasive pattern of social inhibition, feelings of inadequacy, and hypersensitivity to negative evaluation. |
| Dependent personality disorder | A pervasive and excessive need to be taken care of, which leads to submissive and clinging behavior and fears of separation. |
| Obsessive-compulsive personality disorder | A pervasive pattern of preoccupation with orderliness, perfectionism, and mental and interpersonal control, at the expense of flexibility, openness, and efficiency. |

that the next version of the *Diagnostic and Statistical Manual—DSM-5*—should incorporate aspects of a dimensional approach to personality disorders (South et al., in press).

## Personality Disorder Clusters

*DSM-IV-TR* divides the personality disorders into three groups, or clusters; this will probably continue until a strong scientific basis is established for viewing them differently (American Psychiatric Association, 2000). The cluster division is based on resemblance. Cluster A is called the odd or eccentric cluster; it includes paranoid, schizoid, and schizotypal personality disorders. Cluster B is the dramatic, emotional, or erratic cluster; it consists of antisocial, borderline, histrionic, and narcissistic personality disorders. Cluster C is the anxious or fearful cluster; it includes avoidant, dependent, and obsessive-compulsive personality disorders. We follow this order in our review.

## Statistics and Development

Because many people with these problems do not seek help on their own as do those with the Axis I disorders, gathering information about the prevalence of personality disorders is difficult and therefore varies a great deal. For example, *DSM-IV-TR* indicates that personality disorders are found in 0.5% to 2.5% of the general population, 10% to 30% of all individuals served in inpatient settings, and 2% to 10% of those individuals in outpatient settings (American Psychiatric Association, 2000). However, an important population survey suggests that as many as 1 in 10 adults in the United States may have a diagnosable personality disorder (Lenzenweger, Lane, Loranger, & Kessler, 2007), which makes them relatively common (see Table 12.2). Numbers vary somewhat across countries, but worldwide about 6% of adults may have at least one personality disorder (Huang et al., 2009). Differences in prevalence estimates may be the result of surveying people in

**TABLE 12.2** Statistics and Development of Personality Disorders

| Disorder | Prevalence* | Gender Differences† | Course |
|---|---|---|---|
| Paranoid personality disorder | In the clinical population: 4.2%<br>In the general population: 2.3%–2.4% | In the clinical population: More common in males<br>In the general population: No difference | Insufficient information |
| Schizoid personality disorder | In the clinical population: 1.4%<br>In the general population: 1.7%–4.9% | In the clinical population: More common in males<br>In the general population: No difference | Insufficient information |
| Schizotypal personality disorder | In the clinical population: 0.6%<br>In the general population: 0.6%–3.3% | In the clinical population: More common in males<br>In the general population: No difference | Chronic; some go on to develop schizophrenia |
| Antisocial personality disorder | In the clinical population: 3.6%<br>In the general population: 0.7%–1% | In the clinical population: More common in males<br>In the general population: No difference | Dissipates after age 40 (Hare, McPherson, & Forth, 1988) |
| Borderline personality disorder | In the clinical population: 9.3%<br>In the general population: 0.7%–1.6% | In the clinical population: More common in females<br>In the general population: No difference | Symptoms gradually improve if individuals survive into their 30s (Zanarini et al., 2006); approximately 6% die by suicide (Perry, 1993) |
| Histrionic personality disorder | In the clinical population: 1.0%<br>In the general population: >1%–2.0% | In the clinical population: No difference<br>In the general population: No difference | Chronic |
| Narcissistic personality disorder | In the clinical population: 2.3%<br>In the general population: >1% | In the clinical population: More common in males<br>In the general population: No difference | May improve over time (Cooper & Ronningstam, 1992; Gunderson, Ronningstam, & Smith, 1991) |
| Avoidant personality disorder | In the clinical population: 14.7%<br>In the general population: 5.0%–5.2% | In the clinical population: No difference<br>In the general population: No difference | Insufficient information |
| Dependent personality disorder | In the clinical population: 1.4%<br>In the general population: 0.6%–1.5% | In the clinical population: No difference<br>In the general population: No difference | Insufficient information |

*Clinical population data reported in Zimmerman, Rothschild, and Chelminski (2005). General population data reported from two community samples, Lenzenweger et al. (2007) and Torgersen, Kringlen, and Cramer (2001).

†Clinical population data reported in *DSM-IV-TR* (American Psychiatric Association, 2000) and general population data from Lenzenweger et al. (2007).

clinical settings versus surveying the general population—even those not seeking assistance. Similarly, gender differences in the disorders—for example, more women diagnosed with borderline personality disorder and more men identified with antisocial personality disorder—are not apparent when surveying the general population. There may be several reasons for these differences in diagnoses, including bias in diagnoses and differences in help-seeking behavior and tolerance of behavior in a culture. We discuss several of these concerns later in the chapter.

Personality disorders are thought to originate in childhood and continue into the adult years (Cloninger & Svakic, 2009); they are also thought to be so ingrained that an onset is difficult to pinpoint. Maladaptive personality characteristics develop over time into the maladaptive behavior patterns that create distress for the affected person and draw the attention of others. Our relative lack of information about such important features of personality disorders as their developmental course is a repeating theme. The gaps in our knowledge of the course of about half these disorders are visible in Table 12.2. One reason for this dearth of research is that many individuals do not seek treatment in the early developmental phases of their disorder but only after years of distress. This makes it difficult to study people with personality disorders from the beginning, although a few research studies have helped us understand the development of several disorders.

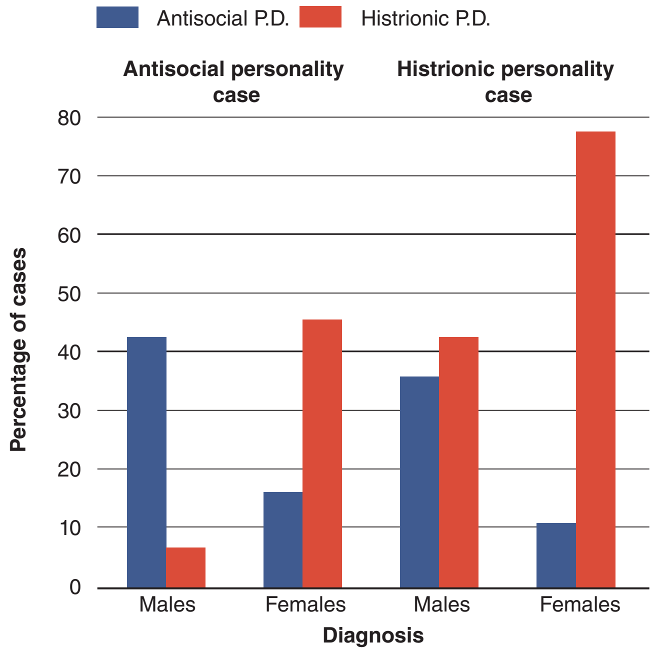
People with borderline personality disorder are characterized by their volatile and unstable relationships; they tend to have persistent problems in early adulthood, with frequent hospitalizations, unstable personal relationships, severe depression, and suicidal gestures. Almost 10% attempt suicide, and approximately 6% succeed in their attempts (Skodol & Gunderson, 2008). On the bright side, their symptoms gradually improve if they survive into their 30s (Zanarini, Frankenburg, Hennen, Reich, & Silk, 2006), although elderly individuals may have difficulty making plans and may be disruptive in nursing homes (Hunt, 2007). People with antisocial personality disorder display a characteristic disregard for the rights and feelings of others; they tend to continue their destructive behaviors of lying and manipulation through adulthood. Fortunately, some tend to "burn out" after the age of about 40 and engage in fewer criminal activities (Douglas, Vincent, & Edens, 2006). As a group, however, the problems of people with personality disorders continue, as shown when researchers follow their progress over the years (Ferguson, 2010b).

## Gender Differences

Borderline personality disorder is diagnosed more often in females (although as you will see next, this may be the result of diagnostic bias), who make up about 75% of the identified cases (Cloninger & Svakic, 2009) (see Table 12.2). Historically, histrionic and dependent personality disorders were identified by clinicians more often in women (Dulit, Marin, & Frances, 1993; Stone, 1993), but according to more recent studies of their prevalence in the general population, equal numbers of males and females may have histrionic and dependent personality disorders (see Table 12.2). If this observation holds up in future studies, why have these disorders been predominantly diagnosed among females in general clinical practice and in other studies?

Do the disparities indicate differences between men and women in certain basic experiences that are genetic, sociocultural, or both, or do they represent biases on the part of the clinicians who make the diagnoses? Take, for example, a classic study by Maureen Ford and Thomas Widiger (1989), who sent fictitious case histories to clinical psychologists for diagnosis. One case described a person with *antisocial personality disorder,* which is characterized by irresponsible and reckless behavior and usually diagnosed in males; the other case described a person with *histrionic personality disorder,* which is characterized by excessive emotionality and attention seeking and more often diagnosed in females. The subject was identified as male in some versions of each case and as female in others, although everything else was identical. As the graph in ■ Figure 12.1 shows, when the antisocial personality disorder case was labeled male, most psychologists gave the correct diagnosis. However, when the same case of antisocial personality disorder was labeled female, most psychologists diagnosed it as histrionic personality disorder rather than antisocial personality disorder. In the case of histrionic personality disorder, being labeled a woman increased the likelihood of that diagnosis. Ford and Widiger (1989) concluded that the psychologists incorrectly diagnosed more women as having histrionic personality disorder.

This gender difference in diagnosis has also been criticized by other authors (see, for example, Kaplan, 1983) on the grounds that histrionic personality disorder, like several of the other personality disorders, is biased against females. As Kaplan (1983) points out, many of the features of histrionic personality disorder,



■ **FIGURE 12.1** Gender bias in diagnosing personality disorders (P.D.). Data are shown for the percentage of cases clinicians rated as antisocial personality disorder or histrionic personality disorder, depending on whether the case was described as a male or a female. (From Ford, M. R., & Widiger, T. A. (1989). Sex bias in the diagnosis of histrionic and antisocial personality disorders. *Journal of Consulting and Clinical Psychology, 57,* 301–305.)

▲ Personality disorders tend to begin in childhood.

such as overdramatization, vanity, seductiveness, and overconcern with physical appearance, are characteristic of the Western "stereotypical female." This disorder may simply be the embodiment of extremely "feminine" traits (Chodoff, 1982); branding such an individual mentally ill, according to Kaplan, reflects society's inherent bias against females. (See Table 12.3 for a humorous take on a male version of a personality disorder.) Interestingly, the "macho" personality (Mosher & Sirkin, 1984), in which the individual possesses stereotypically masculine traits, is nowhere to be found in the *DSM*.

The issue of gender bias in diagnosing personality disorder remains highly controversial. Remember, however, that just because certain disorders are observed more in men or women doesn't necessarily indicate bias (Lilienfeld, VanValkenburg, Larntz, & Akiskal, 1986). When it is present, bias can occur at different stages of the diagnostic process. Widiger and Spitzer (1991) point out that the criteria for the disorder may themselves be biased *(criterion gender bias),* or the assessment measures and the way they are used may be biased *(assessment gender bias).* In general, the criteria themselves do not appear to have strong gender bias (Jane, Oltmanns, South, & Turkheimer, 2007), although there may be some tendency for clinicians to use their own bias when using the criteria and therefore diagnose males and females differently (Morey, Alexander, & Boggs, 2005). As studies continue, researchers will try to make the diagnosis of personality disorders more accurate with respect to gender and more useful to clinicians.

## Comorbidity

Looking at Table 12.2 and adding up the prevalence rates across the personality disorders, you might conclude that up to 25% of all people are affected. In fact, the percentage of people in the population with a personality disorder is likely closer to 10% (Huang et al., 2009; Lenzenweger et al., 2007). What accounts for this discrepancy? A major concern with the personality disorders is that people tend to be diagnosed with more than one. The term *comorbidity* historically describes the condition in which a person has multiple diseases (Caron & Rutter, 1991). A fair amount of disagreement is ongoing about whether the term should be used with psychological disorders because of the frequent overlap of different disorders (Skodol, 2005). In just one example, Zimmerman, Rothschild, and Chelminski (2005) conducted a study of 859 psychiatric outpatients and assessed how many had one or more personality disorders. Table 12.4 shows the odds that a person with a particular personality disorder would also meet the criteria for other disorders. For example, a person identified with borderline personality disorder is also likely to receive diagnoses of paranoid, schizotypal, antisocial, narcissistic, avoidant, and dependent personality disorders.

Do people really tend to have more than one personality disorder? Are the ways we define these disorders inaccurate, and do we need to improve our definitions so that they do not overlap? Or did we divide the disorders in the wrong way, and do we need to rethink the categories? Such questions about comorbidity are just a few of the important issues faced by researchers who study personality disorders.

▲ Gender bias may affect the diagnosis of clinicians who associate certain behavioral characteristics with one sex or the other.

**TABLE 12.3** Diagnostic Criteria for "Independent" Personality Disorder

A. Puts work (career) above relationships with loved ones (for example, travels a lot on business, works late at night and on weekends).
B. Is reluctant to take into account others' needs when making decisions, especially concerning the individual's career or use of leisure time, for example, expects spouse and children to relocate to another city because of individual's career plans.
C. Passively allows others to assume responsibility for major areas of social life because of inability to express necessary emotion (for example, lets spouse assume most child-care responsibilities).

*Source:* From Kaplan, M. (1983). A woman's view of DSM-III. *American Psychologist, 38,* 786–792.

## Personality Disorders under Study

We started this chapter by noting difficulties in categorizing personality disorders; for example, there is much overlap of the categories, which suggests there may be other ways to arrange these pervasive difficulties of character. It shouldn't surprise you to learn that other personality disorders have been studied for inclusion in the *DSM*—for example, sadistic personality disorder, which includes people who receive pleasure by inflicting pain on others (Morey, Hopwood, & Klein, 2007), and self-defeating personality disorder, which includes people who are overly passive and accept the pain and suffering imposed by others (Skodol, 2005). However, few studies support the existence of these disorders, so they were not included in the *DSM-IV-TR* (Cloninger & Svakic, 2009).

Two new personality disorders are under study for inclusion in *DSM-5. Depressive personality disorder* includes self-criticism, dejection, a judgmental stance toward others, and a tendency to feel guilt. Some evidence indicates this may indeed be a personality disorder distinct from dysthymic disorder (the mood disorder described in Chapter 7 that involves a persistently depressed mood lasting at least 2 years); research is continuing in this area (Orstavik, Kendler, Czajkowski, Tambs, & Reichborn-Kjennerud, 2007; Vachon, Sellbom, Ryder, Miller, & Bagby, 2009). *Passive-aggressive (negativistic) personality disorder* is characterized by passive aggression in which people adopt a negativistic attitude to resist routine demands and expectations. This category is an expansion of a previous *DSM-III-R* category, *passive-aggressive personality disorder,* and may be a subtype of a narcissistic personality disorder (Hopwood et al., 2009).

We now review the personality disorders currently in *DSM-IV-TR,* 10 in all. Then we look briefly at a few categories being considered for inclusion in *DSM-5.*

### Concept Check 12.1

Fill in the blanks to complete the following statements about personality disorders.

1. Personality disorders as a group are distinct and therefore placed on a separate axis, ____________.
2. ____________ refers to a condition where people with personality disorders are diagnosed with other disorders.
3. The personality disorders are divided into three clusters or groups: ____________ contains the odd or eccentric disorders; ____________ the dramatic, emotional, and

**TABLE 12.4** Diagnostic Overlap of Personality Disorders

†The "odds ratio" indicates how likely it is that a person would have both disorders. The odds ratios with an asterisk (*) indicate that, statistically, people are likely to be diagnosed with both disorders—with a higher number meaning people are more likely to have both. Some higher odds ratios are not statistically significant because the number of people with the disorder in this study was relatively small.

erratic disorders; and ____________ the anxious and fearful disorders.

4. It's debated whether personality disorders are extreme versions of otherwise normal personality variations (therefore classified as dimensions) or ways of relating that are different from psychologically healthy behavior (classified as ____________).
5. Personality disorders are described as ____________ because unlike many disorders, they originate in childhood and continue throughout adulthood.
6. Although gender differences are evident in the research of personality disorders, some differences in the findings may be the result of ____________.

## Cluster A Personality Disorders

Three personality disorders—paranoid, schizoid, and schizotypal—share common features that resemble some of the psychotic symptoms seen in schizophrenia. These odd or eccentric personality disorders are described next.

### Paranoid Personality Disorder

Although it is probably adaptive to be a little wary of other people and their motives, being too distrustful can interfere with making friends, working with others, and, in general, getting through daily interactions in a functional way. People with **paranoid personality disorder** are excessively mistrustful and suspicious of others, without any justification. They assume other people are out to harm or trick them; therefore, they tend not to confide in others. Consider the case of Jake.

#### **JAKE** | *Research Victim*

Jake grew up in a middle-class neighborhood, and although he never got in serious trouble, he had a reputation in high school for arguing with teachers and classmates. After high school he enrolled in the local community college, but he flunked out after the first year. Jake's lack of success in school was partly attributable to his failure to take responsibility for his poor grades. He began to develop conspiracy theories about fellow students and professors, believing they worked together to see him fail. Jake bounced from job to job, each time complaining that his employer was spying on him at work and at home.

At age 25—and against his parents' wishes—he moved out of his parents' home to a small town out of state. Unfortunately, the letters Jake wrote home daily confirmed his parents' worst fears. He was becoming increasingly preoccupied with theories about people who were out to harm him. Jake spent enormous amounts of time on his computer exploring websites, and he developed an elaborate theory about how research had been performed on him in childhood. His letters home described his belief that researchers working with the CIA drugged him as a child and implanted something in his ear that emitted microwaves. These microwaves, he believed, were being used to cause him to develop cancer. Over 2 years, he became increasingly preoccupied with this theory, writing letters to various authorities trying to convince them he was being slowly killed. After he threatened harm to some local college administrators, his parents were contacted and they brought him to a psychologist, who diagnosed him with paranoid personality disorder and major depression.

#### Clinical Description

The defining characteristic of people with paranoid personality disorder is a pervasive unjustified distrust (Edens, Marcus, & Morey, 2009). Certainly, there may be times when someone is deceitful and "out to get you"; however, people with paranoid personality disorder are suspicious in situations in which most other people would agree their suspicions are unfounded. Even events that have nothing to do with them are interpreted as personal attacks (Bernstein & Useda, 2007). These people would view a neighbor's barking dog or a delayed airline flight as a deliberate attempt to annoy them. Unfortunately, such mistrust often extends to people close to them and makes meaningful relationships difficult. Imagine what a lonely existence this must be. Suspiciousness and mistrust can show themselves in a number of ways. People with paranoid personality disorder may be argumentative, may complain, or may be quiet. This style of interaction is communicated, sometimes nonverbally, to others, often resulting in discomfort among those who come in contact with them because of this volatility. They often appear tense and are "ready to pounce" when they think they've been slighted by someone. These individuals are sensitive to criticism and have an excessive need for autonomy (Bernstein & Useda, 2007).

#### Causes

Evidence for biological contributions to paranoid personality disorder is limited. Some research suggests the disorder may be slightly more common among the relatives of people who have schizophrenia, although the association does not seem to be strong (Tienari et al., 2003). In other words, relatives of individuals with schizophrenia may be more likely to have paranoid personality disorder than people who do not have a relative with schizophrenia. As you will see later with the other odd or eccentric personality disorders in Cluster A, there seems to be some relationship with schizophrenia, although its exact nature is not yet clear. In general, however, there appears to be a strong role for genetics in paranoid personality disorder (Kendler et al., 2006).

Psychological contributions to this disorder are even less certain, although some interesting speculations have been made. Retrospective research—asking people with this disorder to recall events from their childhood—suggests that early mistreatment or traumatic childhood experiences may play a role in the development of paranoid personality disorder (Natsuaki, Cicchetti, & Ro-

### DSM-IV-TR **Table 12.2** Diagnostic Criteria for Paranoid Personality Disorder

**A.** A pervasive distrust and suspiciousness of others such that their motives are interpreted as malevolent, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:

  1. Suspects, without sufficient basis, that others are exploiting, harming, or deceiving him or her
  2. Is preoccupied with unjustified doubts about the loyalty or trustworthiness of friends or associates
  3. Is reluctant to confide in others because of unwarranted fear that the information will be used maliciously against him or her
  4. Reads hidden demeaning or threatening meanings into benign remarks or events
  5. Persistently bears grudges, i.e., is unforgiving of insults, injuries, or slights
  6. Perceives attacks on his or her character or reputation that are not apparent to others and is quick to react angrily or to counterattack
  7. Has recurrent suspicions, without justification, regarding fidelity of spouse or sexual partner

**B.** Does not occur exclusively during the course of schizophrenia, a mood disorder with psychotic features, or another psychotic disorder and is not due to the direct physiological effects of a general medical condition.

*Note:* If criteria are met prior to the onset of schizophrenia, add "premorbid," e.g., "paranoid personality disorder (premorbid)."

*Source:* Reprinted, with permission, from American Psychiatric Association. (2000). *Diagnostic and statistical manual of mental disorders* (4th ed., text revision). Washington, DC: Author, © 2000 American Psychiatric Association.

gosch, 2009). Caution is warranted when interpreting these results because, clearly, there may be strong bias in the recall of these individuals, who are already prone to viewing the world as a threat.

Some psychologists point directly to the thoughts of people with paranoid personality disorder as a way of explaining their behavior. One view is that people with this disorder have the following basic mistaken assumptions about others: "People are malevolent and deceptive," "They'll attack you if they get the chance," and "You can be okay only if you stay on your toes" (Freeman, Pretzer, Fleming, & Simon, 1990). This is a maladaptive way to view the world, yet it seems to pervade every aspect of the lives of these individuals. Although we don't know why they develop these perceptions, some speculation is that the roots are in their early upbringing. Their parents may teach them to be careful about making mistakes and may impress on them that they are different from other people. This vigilance causes them to see signs that other people are deceptive and malicious (Carroll, 2009). It is certainly true that people are not always benevolent and sincere, and our interactions are sometimes ambiguous enough to make other people's intentions unclear. Looking too closely at what other people say and do can sometimes lead you to misinterpret them.

Cultural factors have also been implicated in paranoid personality disorder. Certain groups of people, such as prisoners, refugees, people with hearing impairments, and older adults, are thought to be particularly susceptible because of their unique experiences (Rogler, 2007). Imagine how you might view other people if you were an immigrant who had difficulty with the language and the customs of your new culture. Such innocuous things as other people laughing or talking quietly might be interpreted as somehow directed at you. The late musician Jim Morrison of The Doors described this phenomenon in his song

Text not available due to copyright restrictions

You have seen how someone could misinterpret ambiguous situations as malevolent. Therefore, cognitive and cultural factors may interact to produce the suspiciousness observed in some people with paranoid personality disorder.

### *Treatment*

Because people with paranoid personality disorder are mistrustful of everyone, they are unlikely to seek professional help when they need it and they have difficulty developing the trusting relationships necessary for successful therapy (Skodol & Gunderson, 2008). Establishing a meaningful therapeutic alliance between the client and the therapist therefore becomes an important first step

▲ People with paranoid personality disorder often believe that impersonal situations exist specifically to annoy or otherwise disturb them.

©Michael Newman/PhotoEdit

(Bender, 2005). When these individuals finally do seek therapy, the trigger is usually a crisis in their lives—such as Jake's threats to harm strangers—or other problems such as anxiety or depression, not necessarily their personality disorder (Kelly, Casey, Dunn, Ayuso-Mateos, & Dowrick, 2007).

Therapists try to provide an atmosphere conducive to developing a sense of trust (Bender, 2005). They often use cognitive therapy to counter the person's mistaken assumptions about others, focusing on changing the person's beliefs that all people are malevolent and most people cannot be trusted (Skodol & Gunderson, 2008). Be forewarned, however, that to date there are no confirmed demonstrations that any form of treatment can significantly improve the lives of people with paranoid personality disorder. A survey of mental health professionals indicated that only 11% of therapists who treat paranoid personality disorder thought these individuals would continue in therapy long enough to be helped (Quality Assurance Project, 1990).

## Schizoid Personality Disorder

Do you know someone who is a "loner"? Someone who would choose a solitary walk over an invitation to a party? A person who comes to class alone, sits alone, and leaves alone? Now, magnify this preference for isolation many times over and you can begin to grasp the impact of **schizoid personality disorder** (Cloninger & Svakic, 2009). People with this personality disorder show a pattern of detachment from social relationships and a limited range of emotions in interpersonal situations. They seem aloof, cold, and indifferent to other people. The term *schizoid* is relatively old, having been used by Bleuler (1924) to describe people who have a tendency to turn inward and away from the outside world. These people were said to lack emotional expressiveness and pursued vague interests. Consider the case of Mr. Z.

### **MR. Z.** | *All on His Own*

A 39-year-old scientist was referred after his return from a tour of duty in Antarctica where he had stopped cooperating with others, withdrawn to his room, and begun drinking on his own. Mr. Z. was orphaned at 4 years, raised by an aunt until 9, and subsequently looked after by an aloof housekeeper. At university he excelled at physics, but chess was his only contact with others. Throughout his subsequent life he made no close friends and engaged primarily in solitary activities. Until the tour of duty in Antarctica, he had been quite successful in his research work in physics. He was now, some months after his return, drinking at least a bottle of Schnapps each day, and his work had continued to deteriorate. He presented as self-contained and unobtrusive and was difficult to engage effectively. He was at a loss to explain his colleagues' anger at his aloofness in Antarctica and appeared indifferent to their opinion of him. He did not appear to require any interpersonal relations, although he did complain of some tedium in his life and at one point during the interview became sad, expressing longing to see his uncle in Germany, his only living relation.

(Cases and excerpts reprinted, with permission of the Royal Australian and New Zealand College of Psychiatrists, from Quality Assurance Project (1990). Treatment outlines for paranoid, schizotypal and schizoid personality disorders. *Australian and New Zealand Journal of Psychiatry, 24,* 339–350.)

### Clinical Description

Individuals with schizoid personality disorder seem neither to desire nor to enjoy closeness with others, including romantic or sexual relationships. As a result they appear cold and detached and do not seem affected by praise or criticism. One of the changes in *DSM-IV-TR* from previous versions is the recognition that at least some people with schizoid personality disorder are sensitive to the opinions of others but are unwilling or unable to express this emotion. For them, social isolation may be extremely painful. Unfortunately, homelessness appears to be prevalent among people with this personality disorder, perhaps as a result of their lack of close friendships and lack of dissatisfaction about not having a sexual relationship with another person (Rouff, 2000).

The social deficiencies of people with schizoid personality disorder are similar to those of people with paranoid personality disorder, although they are more extreme. As Beck and Freeman (1990, p. 125) put it, they "consider themselves to be observers rather than participants in the world around them." They do not seem to have the unusual thought processes that characterize the other disorders in Cluster A (Cloninger & Svakic, 2009) (see Table 12.5). For example, people with paranoid and schizotypal personality disorders often have *ideas of reference,* mistaken beliefs that meaningless events relate just to them. In contrast, those with schizoid personality disorder share the social isolation, poor rapport, and constricted affect (showing neither positive nor negative emotion) seen in people with paranoid personality disorder. You will see in Chapter 13 that this distinction among psychotic-like symptoms is important to understanding people with schizophrenia, some of whom show the "positive" symptoms (actively unusual behaviors such as ideas of reference) and others only the "negative" symptoms (the more passive manifestations of social isolation or poor rapport with others).

**TABLE 12.5** Grouping Schema for Cluster A Disorders

| | **Psychotic-Like Symptoms** | |
|---|---|---|
| **Cluster A Personality Disorder** | **Positive (for example, Ideas of Reference, Magical Thinking, and Perceptual Distortions)** | **Negative (for example, Social Isolation, Poor Rapport, and Constricted Affect)** |
| Paranoid | Yes | Yes |
| Schizoid | No | Yes |
| Schizotypal | Yes | No |

**DSM-IV-TR**

### **Table 12.3** Diagnostic Criteria for Schizoid Personality Disorder

**A.** A pervasive pattern of detachment from social relationships and a restricted range of expression of emotions in interpersonal settings, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:

  1. Neither desires nor enjoys close relationships, including being part of a family
  2. Almost always chooses solitary activities
  3. Has little, if any, interest in having sexual experiences with another person
  4. Takes pleasure in few, if any, activities
  5. Lacks close friends or confidants other than first-degree relatives
  6. Appears indifferent to the praise or criticism of others
  7. Shows emotional coldness, detachment, or flattened affectivity

**B.** Does not occur exclusively during the course of schizophrenia, a mood disorder with psychotic features, another psychotic disorder, or a pervasive developmental disorder and is not due to the direct physiological effects of a general medical condition.

*Note:* If criteria are met prior to the onset of schizophrenia, add “premorbid,” e.g., “schizoid personality disorder (premorbid).”

*Source:* Reprinted, with permission, from American Psychiatric Association. (2000). *Diagnostic and statistical manual of mental disorders* (4th ed., text revision). Washington, DC: Author, © 2000 American Psychiatric Association.

### *Causes and Treatment*

Extensive research on the genetic, neurobiological, and psychosocial contributions to schizoid personality disorder remains to be conducted (Phillips, Yen, & Gunderson, 2003). Childhood shyness is reported as a precursor to later adult schizoid personality disorder. It may be that this personality trait is inherited and serves as an important determinant in the development of this disorder. Abuse and neglect in childhood are also reported among individuals with this disorder (Johnson, Bromley, & McGeoch, 2005). Research over the past several decades point to biological causes of autism (a disorder we discuss in more detail in Chapter 14), and parents of children with autism are more likely to have schizoid personality disorder (Constantino et al., 2009). It is possible that a biological dysfunction found in both autism and schizoid personality disorder combines with early learning or early problems with interpersonal relationships to produce the social deficits that define schizoid personality disorder.

It is rare for a person with this disorder to request treatment except in response to a crisis such as extreme depression or losing a job (Kelly et al., 2007). Therapists often begin treatment by pointing out the value in social relationships. The person with the disorder may even need to be taught the emotions felt by others to learn empathy (Skodol & Gunderson, 2008). Because their social skills were never established or have atrophied through lack of use, people with schizoid personality disorder often receive social skills training. The therapist takes the part of a friend or significant other in a technique known as role-playing and helps the patient practice establishing and maintaining social relationships (Skodol & Gunderson, 2008). This type of social skills training is helped by identifying a social network—a person or people who will be supportive (Bender, 2005). Outcome research on this type of approach is unfortunately quite limited, so we must be cautious in evaluating the effectiveness of treatment for people with schizoid personality disorder.

## Schizotypal Personality Disorder

People with **schizotypal personality disorder** are typically socially isolated, like those with schizoid personality disorder. In addition, they also behave in ways that would seem unusual to many of us, and they tend to be suspicious and to have odd beliefs (Cloninger & Svakic, 2009). Schizotypal personality disorder is considered by some to be on a continuum (that is, on the same spectrum) with schizophrenia—the severe disorder we discuss in the next chapter—but without some of the more debilitating symptoms, such as hallucinations and delusions. Consider the case of Mr. S.

### **MR. S.** | *Man With a Mission*

Mr. S. was a 35-year-old chronically unemployed man who had been referred by a physician because of a vitamin deficiency. This was thought to have eventuated because Mr. S. avoided any foods that “could have been contaminated by machine.” He had begun to develop alternative ideas about diet in his 20s and soon left his family and began to study an Eastern religion. “It opened my third eye; corruption is all about,” he said.

He now lived by himself on a small farm, attempting to grow his own food, bartering for items he could not grow himself. He spent his days and evenings researching the origins and mechanisms of food contamination and, because of this knowledge, had developed a small band who followed his ideas. He had never married and maintained little contact with his family: “I’ve never been close to my father. I’m a vegetarian.”

He said he intended to do a herbalism course to improve his diet before returning to his life on the farm. He had refused medication from the physician and became uneasy when the facts of his deficiency were discussed with him.

(Cases and excerpts reprinted, with permission of the Royal Australian and New Zealand College of Psychiatrists, from Quality Assurance Project, 1990. Treatment outlines for paranoid, schizotypal and schizoid personality disorders. *Australian and New Zealand Journal of Psychiatry, 24,* 339–350.)

### *Clinical Description*

People given a diagnosis of schizotypal personality disorder have psychotic-like (but not psychotic) symptoms (such as believing everything relates to them personally), social deficits, and sometimes cognitive impairments or paranoia (Cloninger & Svakic, 2009). These individuals are often considered odd or bizarre because of how they relate to other people, how they think and behave, and even how they dress. They have *ideas of reference,* which means they think insignificant events relate directly to them. For example, they may believe that somehow everyone on a passing city bus is talking about them, yet they may be able to acknowledge this is unlikely. Again, as you will see in Chapter 13, some people with schizophrenia also have ideas of reference, but they are usually not able to "test reality" or see the illogic of their ideas.

Individuals with schizotypal personality disorder also have odd beliefs or engage in "magical thinking," believing, for example, that they are clairvoyant or telepathic. In addition, they report unusual perceptual experiences, including such illusions as feeling the presence of another person when they are alone. Notice the subtle but important difference between *feeling* as if someone else is in the room and the more extreme perceptual distortion in people with schizophrenia who might report there *is* someone else in the room when there isn't. Unlike people who simply have unusual interests or beliefs, those with schizotypal personality disorder tend to be suspicious and have paranoid thoughts, express little emotion, and may dress or behave in unusual ways (for example, wear many layers of clothing in the summertime or mumble to themselves) (Cloninger & Svakic, 2009). Prospective research on children who later develop schizotypal personality disorder found that they tend to be passive and unengaged and are hypersensitive to criticism (Olin et al., 1997).

**DSM-IV-TR**

### **Table 12.4** Diagnostic Criteria for Schizotypal Personality Disorder

**A.** A pervasive pattern of social and interpersonal deficits marked by acute discomfort with, and reduced capacity for, close relationships, as well as by cognitive or perceptual distortions and eccentricities of behavior, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

  1. Ideas of reference (excluding delusions of reference)
  2. Odd beliefs or magical thinking that influences behavior and is inconsistent with subcultural norms (e.g., superstitiousness, belief in clairvoyance, telepathy, or "sixth sense"; in children and adolescents, bizarre fantasies or preoccupations)
  3. Unusual perceptual experiences, including bodily illusions
  4. Odd thinking and speech (e.g., vague, circumstantial, metaphorical, overelaborate, or stereotyped)
  5. Suspiciousness or paranoid ideation
  6. Inappropriate or constricted affect
  7. Behavior or appearance that is odd, eccentric, or peculiar
  8. Lack of close friends or confidants other than first-degree relatives
  9. Excessive social anxiety that does not diminish with familiarity and tends to be associated with paranoid fears rather than negative judgments about self

**B.** Does not occur exclusively during the course of schizophrenia, a mood disorder with psychotic features, another psychotic disorder, or a pervasive developmental disorder.

*Note:* If criteria are met prior to the onset of schizophrenia, add "premorbid," e.g., "schizotypal personality disorder (premorbid)."

*Source:* Reprinted, with permission, from American Psychiatric Association. (2000). *Diagnostic and statistical manual of mental disorders* (4th ed., text revision). Washington, DC: Author, © 2000 American Psychiatric Association.

Clinicians must be aware that different cultural beliefs or practices may lead to a mistaken diagnosis of schizotypal personality disorder. For example, some people who practice certain religious rituals—such as speaking in tongues, practicing voodoo, or mind reading—may do so with such obsessiveness as to make them seem extremely unusual, thus leading to a misdiagnosis (American Psychiatric Association, 2000). Mental health workers have to be particularly sensitive to cultural practices that may differ from their own and can distort their view of certain seemingly unusual behaviors.

### Causes

Historically, the word *schizotype* was used to describe people who were predisposed to develop schizophrenia (Meehl, 1962; Rado, 1962). Schizotypal personality disorder is viewed by some to be one phenotype of a schizophrenia genotype. Recall that a *phenotype* is one way a person's genetics is expressed. A *genotype* is the gene or genes that make up a particular disorder. However, depending on a variety of other influences, the way you turn out—your phenotype—may vary from other people with a similar genetic makeup. Some people are thought to have "schizophrenia genes" (the genotype) yet, because of the relative lack of biological influences (for example, prenatal illnesses) or environmental stresses (for example, poverty), some will have the less severe schizotypal personality disorder (the phenotype).

The idea of a relationship between schizotypal personality disorder and schizophrenia arises partly from the way people with the disorders behave. Many characteristics of schizotypal personality disorder, including ideas of reference, illusions, and paranoid thinking, are similar but milder forms of behaviors observed among people with schizophrenia. Genetic research also seems to support a relationship. Family, twin, and adoption studies have shown an increased prevalence of schizotypal personality disorder among relatives of people with schizophrenia who do not also have schizophrenia themselves (Siever & Davis, 2004). However, these studies also tell us that the environment can strongly influence schizotypal personality disorder. Some research suggests that schizotypal symptoms are strongly associated with childhood maltreatment among men and this childhood maltreatment seems to result in posttraumatic stress disorder (PTSD) symptoms (see Chapter 5) among women (Berenbaum, Thompson, Milanak, Boden, & Bredemeier, 2008). Cognitive assessment of people with this disorder points to mild to moderate decrements in their ability to perform on tests involving memory and learning, suggesting some damage in the left hemisphere (Siever & Davis, 2004). Other research, using magnetic resonance imaging, points to generalized brain abnormalities in those with schizotypal personality disorder (Modinos et al., 2009).

### Treatment

Some estimate that between 30% and 50% of the people with schizotypal personality disorder who request clinical help also meet the criteria for major depressive disorder. Treatment includes some of the medical and psychological treatments for depression (Cloninger & Svakic, 2009; Mulder, Frampton, Luty, & Joyce, 2009).

Controlled studies of attempts to treat groups of people with schizotypal personality disorder are few. However, there is now growing interest in treating this disorder because it is being viewed as a precursor to schizophrenia (McClure et al., 2010). One study used a combination of approaches, including antipsychotic medication, community treatment (a team of support professionals providing therapeutic services), and social skills training, to treat the symptoms experienced by individuals with this disorder. Researchers found that this combination of approaches either reduced their symptoms or postponed the onset of later schizophrenia (Nordentoft et al., 2006).

Further research on the treatment of people with this disorder is important for a variety of reasons. They tend not to improve over time, and, as you have seen, some evidence indicates that some will go on to develop the more severe characteristics of schizophrenia.

### Concept Check 12.2

Which personality disorders are described here?

1. Heidi trusts no one and wrongly believes other people want to harm her or cheat her out of her life earnings. She is sure her husband is secretly planning to leave her and take their three boys, although she has no proof. She no longer confides in friends or divulges any information to coworkers for fear that it will be used in a plot against her. She is usually tense and ready to argue about harmless comments made by family members. ____________
2. Rebecca lives alone out in the country with her birds and has little contact with relatives or any other individuals in a nearby town. She is extremely concerned with pollution, fearing that harmful chemicals are in the air and water around her. She has developed her own water purification system and makes her own clothes. If it is necessary for her to go outside, she covers her body with excessive clothing and wears a face mask to avoid the contaminated air. ____________
3. Doug is a college student who has no close friends. He comes to class every day and sits in a corner and is sometimes seen having lunch alone on the park bench. Most students find him difficult to engage and complain about his lack of involvement in class activities but he appears indifferent to what others say. He has never had a girlfriend, and expresses no desire to have sex. He is meeting with a therapist only because his family tricked him into going. ____________

## Cluster B Personality Disorders

People diagnosed with the Cluster B personality disorders—antisocial, borderline, histrionic, and narcissistic—all have behaviors that have been described as dramatic, emotional, or erratic. These personality disorders are described next.

### Antisocial Personality Disorder

People with **antisocial personality disorder** are among the most puzzling of the individuals a clinician will see in a practice and are characterized as having a history of failing to comply with social norms. They perform actions most of us would find unacceptable, such as stealing from friends and family. They also tend to be irresponsible, impulsive, and deceitful (De Brito & Hodgins, 2009). Robert Hare, a pioneer in the study of people with this disorder, describes them as "social predators who charm, manipulate, and ruthlessly plow their way through life, leaving a broad trail of broken hearts, shattered expectations, and empty wallets. Completely lacking in conscience and empathy, they selfishly take what they want and do as they please, violating social norms and expectations without the slightest sense of guilt or regret" (Hare, 1993, p. xi). Just who are these people with antisocial personality disorder? Consider the case of Ryan.

### RYAN *The Thrill Seeker*

I first met Ryan on his 17th birthday. Unfortunately, he was celebrating the event in a psychiatric hospital. He had been truant from school for several months and had gotten into some trouble; the local judge who heard his case had recommended psychiatric evaluation one more time, even though Ryan had been hospitalized six previous times, all for problems related to drug use and truancy. He was a veteran of the system and already knew most of the staff. I interviewed him to assess why he was admitted this time and to recommend treatment.

My first impression was that Ryan was cooperative and pleasant. He pointed out a tattoo on his arm that he had made himself, saying that it was a "stupid" thing to have done and that he now regretted it. He regretted many things and was looking forward to moving on with his life. I later found out that he was never truly remorseful for anything.

Our second interview was quite different. In the 48 hours since our first interview, Ryan had done a number of things that showed why he needed a great deal of help. The most serious incident involved a 15-year-old girl named Ann who attended class with Ryan in the hospital school. Ryan had told her that he was going to get himself discharged, get in trouble, and be sent to the same prison Ann's father was in, where he would rape her father. Ryan's threat so upset Ann that she hit her teacher and several of the staff. When I spoke to Ryan about this, he smiled slightly and said he was bored and that it was fun to upset Ann. When I asked whether it bothered him that his behavior might extend her stay in the hospital, he looked puzzled and said, "Why should it bother me? She's the one who'll have to stay in this hell hole!"

Just before Ryan's admittance, a teenager in his town was murdered. A group of teens went to the local cemetery at night to perform satanic rituals, and a young man was stabbed to death, apparently over a drug purchase. Ryan was in the group, although he did not stab the boy. He told me that they occasionally dug up graves to get skulls for their parties—not because they really believed in the devil but because it was fun and it scared the younger kids. I asked, "What if this was the grave of someone you knew, a relative or a friend? Would it bother you that strangers were digging up the remains?" He shook his head. "They're dead, man; they don't care. Why should I?"

Ryan told me he loved PCP, or "angel dust," and that he would rather be dusted than anything else. He routinely made the 2-hour trip to New York City to buy drugs in a particularly dangerous neighborhood. He denied that he was ever nervous. This wasn't machismo; he really seemed unconcerned.

Ryan made little progress. I discussed his future in family therapy sessions and we talked about his pattern of showing supposed regret and remorse and then stealing money from his parents and going back onto the street. Most of our discussions centered on trying to give his parents the courage to say no to him and not to believe his lies.

One evening, after many sessions, Ryan said he had seen the "error of his ways" and that he felt bad he had hurt his parents. If they would only take him home this one last time, he would be the son he should have been all these years. His speech moved his parents to tears, and they looked at me gratefully as if to thank me for curing their son. When Ryan finished talking, I smiled, applauded, told him it was the best performance I had ever seen. His parents turned on me in anger. Ryan paused for a second, then he, too, smiled and said, "It was worth a shot!" Ryan's parents were astounded that he had again tricked them into believing him; he hadn't meant a word of what he had just said. Ryan was eventually discharged to a drug rehabilitation program. Within 4 weeks, he had convinced his parents to take him home, and within 2 days he had stolen all their cash and disappeared; he apparently went back to his friends and to drugs.

When he was in his 20s, after one of his many arrests for theft, he was diagnosed as having antisocial personality disorder. His parents never summoned the courage to turn him out or refuse him money, and he continues to con them into providing him with a means of buying more drugs.

### Clinical Description

Individuals with antisocial personality disorder tend to have long histories of violating the rights of others (De Brito & Hodgins, 2009). They are often described as being aggressive because they take what they want, indifferent to the concerns of other people. Lying and cheating seem to be second nature to them, and often they appear unable to tell the difference between the truth and the lies they make up to further their own goals. They show no remorse or concern over the sometimes devastating effects of their actions. Substance abuse is common, occurring in 60% of people with antisocial personality disorder, and appears to be a lifelong pattern among these individuals (Taylor & Lang, 2006). The long-term outcome for people with antisocial personality disorder is usually poor, regardless of gender (Colman et al., 2009). One classic study, for example, followed 1,000 delinquent and nondelinquent boys over a 50-year period (Laub & Vaillant, 2000). Many of the delinquent boys would today receive a diagnosis of conduct disorder, which you will see later may be a precursor to antisocial personality disorder in adults. The delinquent boys were more than twice as likely to die an unnatural death (for example, accident, suicide, or homicide) as their nondelinquent peers, which may be attributed to factors such as alcohol abuse and poor self-care (for example, infections and reckless behavior).

Antisocial personality disorder has had a number of names over the years. Philippe Pinel (1801/1962) identified what he called *manie sans délire* (mania without delirium) to describe people with unusual emotional responses and impulsive rages but no deficits in reasoning ability (Charland, 2010). Other labels have included moral insanity, egopathy, sociopathy, and psychopathy. A great deal has been written about these labels; we focus on the two that have figured most prominently in psychological research: **psychopathy** and *DSM-IV-TR*'s antisocial personality disorder. As you will see, there are important differences between the two.

**Defining Criteria** Hervey Cleckley (1941/1982), a psychiatrist who spent much of his career working with the "psychopathic personality," identified a constellation of 16 major characteristics, most of which are personality traits and are sometimes referred to as the "Cleckley criteria." Hare and his colleagues, building on the descriptive work of Cleckley, researched the nature of psychopathy (see, for example, Hare, 1970; Harpur, Hare, & Hakstian, 1989) and developed a 20-item checklist that serves as

**DSM-IV-TR** **Table 12.5** Diagnostic Criteria for Antisocial Personality Disorder

**A.** There is a pervasive pattern of disregard for and violation of the rights of others occurring since age 15 years, as indicated by three (or more) of the following:
  **1.** Failure to conform to social norms with respect to lawful behaviors as indicated by repeatedly performing acts that are grounds for arrest
  **2.** Deceitfulness, as indicated by repeated lying, use of aliases, or conning others for personal profit or pleasure
  **3.** Impulsivity or failure to plan ahead
  **4.** Irritability and aggressiveness, as indicated by repeated physical fights or assaults
  **5.** Reckless disregard for safety of self or others
  **6.** Consistent irresponsibility, as indicated by repeated failure to sustain consistent work behavior or honor financial obligations
  **7.** Lack of remorse, as indicated by being indifferent to or rationalizing having hurt, mistreated, or stolen from another

**B.** The individual is at least age 18 years.

**C.** There is evidence of conduct disorder with onset before age 15 years.

**D.** The occurrence of antisocial behavior is not exclusively during the course of schizophrenia or a manic episode.

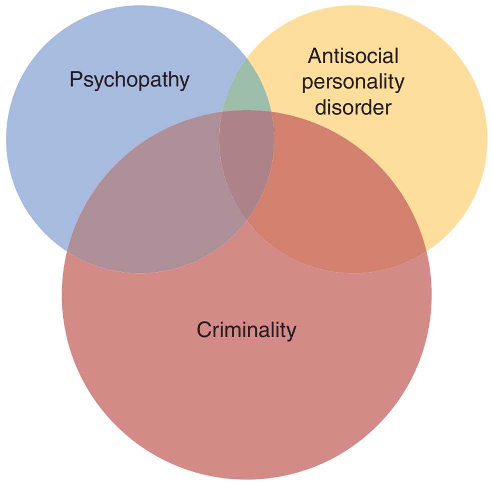
an assessment tool. Six of the criteria that Hare includes in his Revised Psychopathy Checklist (PCL-R) are as follows:

1. Glibness/superficial charm
2. Grandiose sense of self-worth
3. Proneness to boredom/need for stimulation
4. Pathological lying
5. Conning/manipulative
6. Lack of remorse

(Neumann, Hare, & Newman, 2007: pg. 103)

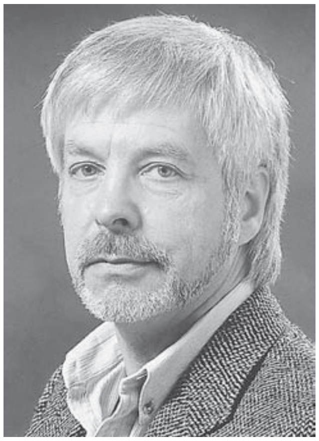
With some training, clinicians are able to gather information from interviews with a person, along with material from significant others or institutional files (for example, prison records), and assign the person scores on the checklist, with high scores indicating psychopathy (Hare & Neumann, 2006).

The *DSM-IV-TR* criteria for antisocial personality focus almost entirely on observable *behaviors* (for example, "impulsively and repeatedly changes employment, residence, or sexual partners"). In contrast, the Cleckley/Hare criteria focus primarily on underlying *personality traits* (for example, being self-centered or manipulative). *DSM-IV-TR* and previous versions chose to use only observable behaviors so that clinicians could reliably agree on a diagnosis. The framers of the criteria felt that trying to assess a personality trait—for example, whether someone was manipulative—would be more difficult than determining whether the person engaged in certain behaviors, such as repeated fighting.



■ **FIGURE 12.2** Overlap and lack of overlap among antisocial personality disorder, psychopathy, and criminality.

**Antisocial Personality, Psychopathy, and Criminality** Although Cleckley did not deny that many psychopaths are at greatly elevated risk for criminal and antisocial behaviors, he did emphasize that some have few or no legal or interpersonal difficulties. In other words, some psychopaths are not criminals and some do not display the aggressiveness that is a *DSM-IV-TR* criterion for antisocial personality disorder. Although the relationship between psychopathic personality and antisocial personality disorder is uncertain, the two syndromes clearly do not overlap perfectly (De Brito & Hodgins, 2009). ■ Figure 12.2 illustrates the relative overlap among the characteristics of psychopathy as described by Cleckley and Hare, antisocial personality disorder as outlined in *DSM-IV-TR,* and criminality, which includes all people who get into trouble with the law.



Courtesy of Robert Hare

▲ Robert Hare has made extensive studies of people with psychopathic personalities.

As you can see in the diagram, not everyone who has psychopathy or antisocial personality disorder becomes involved with the legal system. What separates many in this group from those who get into trouble with the law may be their intelligence quotient (IQ). In a classic prospective, longitudinal study, White, Moffitt, and Silva (1989) followed almost 1,000 children, beginning at age 5, to see what predicted antisocial behavior at age 15. They found that, of the 5-year-olds determined to be at high risk for later delinquent behavior, 16% did indeed have run-ins with the law by the age of 15 and 84% did not. What distinguished these two groups? In general, the at-risk children with lower IQs were the ones who got in trouble. This suggests that having a higher IQ may help protect some people from developing more serious problems, or may at least prevent them from getting caught.

Some psychopaths function quite successfully in certain segments of society (for example, politics, business, and entertainment). Because of the difficulty in identifying these people, such "successful" or "subclinical" psychopaths (who meet some of the criteria for psychopathy) have not been the focus of much research. In a clever exception, Widom (1977; pg. 677) recruited a sample of subclinical psychopaths through advertisements in underground newspapers that invited many of the major personality characteristics of psychopathy. For example, one of the advertisements read as follows:

> Wanted: charming, aggressive, carefree people who are impulsively irresponsible but are good at handling people and at looking after number one.

Widom found that her sample appeared to possess many of the same characteristics as imprisoned psychopaths; for example, a large percentage of them received low scores on questionnaire measures of empathy and socialization and their parents tended to have higher rates of psychopathology, including alcoholism. But many of these individuals had stable occupations and had managed to stay out of prison. Widom's study, although lacking a control group, shows that at least some individuals with psychopathic personality traits avoid repeated contact with the legal system and may even function successfully in society.

Identifying psychopaths among the criminal population seems to have important implications for predicting their future criminal behavior. As you can imagine, having personality characteristics such as a lack of remorse and impulsivity can lead to difficulty

staying out of trouble with the legal system. In general, people who score high on measures of psychopathy commit crimes at a higher rate than those with lower scores and are at greater risk for more violent crimes and recidivism (repeating offenses) (Widiger, 2006).

As we review the literature on antisocial personality disorder, note that the people included in the research may be members of only one of the three groups (those with antisocial personality disorder, psychopathy, and criminals) we have described. For example, genetic research is usually conducted with criminals because they and their families are easier to identify than members of the other groups. As you now know, the criminal group may include people other than those with antisocial personality disorder or psychopathy. Keep this in mind as you read on.

**Conduct Disorder** Before we discuss causal factors, it is important to note the developmental nature of antisocial behavior. *DSM-IV-TR* provides a separate diagnosis for children who engage in behaviors that violate society's norms: *conduct disorder*. Many children with conduct disorder—most often diagnosed in boys—become juvenile offenders and tend to become involved with drugs (Durand, in press). Ryan fit into this category. More important, the lifelong pattern of antisocial behavior is evident because young children who display antisocial behavior are likely to continue these behaviors as they grow older (Soderstrom, Sjodin, Carlstedt, & Forsman, 2004). Data from long-term follow-up research indicate that many adults with antisocial personality disorder or psychopathy had conduct disorder as children (Robins, 1978; Salekin, 2006); the likelihood of an adult having antisocial personality disorder increases if, as a child, he or she had both conduct disorder and attention deficit/hyperactivity disorder (Biederman, Mick, Faraone, & Burback, 2001; Moffitt, Caspi, Rutter, & Silva, 2001). In many cases, the types of norm violations that an adult would engage in—irresponsibility regarding work or family—appear as younger versions in conduct disorder, such as truancy from school or running away from home. A major difference is that lack of remorse is included under antisocial personality disorder but not in the conduct disorder criteria. That is, unlike those with antisocial personality disorder, some children with conduct disorder do feel remorseful about their behavior.

There is a tremendous amount of interest in studying a group that causes a great deal of harm to society. Research has been conducted for a number of years, and so we know a great deal more about antisocial personality disorder than about most of the other personality disorders.

#### Genetic Influences

Family, twin, and adoption studies all suggest a genetic influence on both antisocial personality disorder and criminality (Ferguson, 2010a). For example in a classic study, Crowe (1974) examined children whose mothers were felons and who were later adopted by other families and compared them with adopted children of normal mothers. All were separated from their mothers as newborns, minimizing the possibility that environmental factors from their biological families were responsible for the results. Crowe found that the adopted offspring of felons had significantly higher rates of arrests, conviction, and antisocial personality than did the adopted offspring of normal mothers, which suggests at least some genetic influence on criminality and antisocial behavior.

However, Crowe found something else quite interesting: The adopted children of felons who themselves later became criminals had spent more time in interim orphanages than either the adopted children of felons who did not become criminals or the adopted children of normal mothers. As Crowe points out, this suggests a gene–environment interaction; in other words, genetic factors may be important only in the presence of certain environmental influences (alternatively, certain environmental influences are important only in the presence of certain genetic predispositions). Genetic factors may present a vulnerability, but actual development of criminality may require environmental factors, such as a deficit in early, high-quality contact with parents or parent surrogates.

This gene–environment interaction was demonstrated most clearly by Cadoret, Yates, Troughton, Woodworth, and Stewart (1995), who studied adopted children and their likelihood of developing conduct problems. If the children's biological parents had a history of antisocial personality disorder and their adoptive families exposed them to chronic stress through marital, legal, or psychiatric problems, the children were at greater risk for conduct problems. Again, research shows that genetic influence does not necessarily mean certain disorders are inevitable. Large-scale research on twins with conduct disorder supports the role of genetic and environmental influences on this disorder as well (Thomas, 2009).

If you remember back to Chapter 4, we introduced the concept of an *endophenotype*—underlying aspects of a disorder that might be more directly influenced by genes. In the case of antisocial personality disorder, gene researchers are looking for genetic differences that may influence factors such as serotonin and dopamine levels or the relative lack of anxiety or fear seen in these individuals (which we discuss next) (van Goozen, Fairchild, Snoek, & Harold, 2007; Waldman & Rhee, 2006). Although at its

### DSM-IV-TR **Table 12.6** Diagnostic Criteria for Conduct Disorder

**A.** A repetitive and persistent pattern of behavior in which the basic rights of others or major age-appropriate societal norms or rules are violated, as manifested by the presence of three (or more) of the following criteria in the past 12 months with at least one criterion present in the past 6 months:

Aggression to people and animals

**1.** Often bullies, threatens, or intimidates others
**2.** Often initiates physical fights
**3.** Has used a weapon that can cause serious physical harm to others (e.g., a bat, brick, broken bottle, knife, gun)
**4.** Has been physically cruel to people
**5.** Has been physically cruel to animals
**6.** Has stolen while confronting a victim (e.g., mugging, purse snatching, extortion, armed robbery)
**7.** Has forced someone into sexual activity

Destruction of property

**8.** Has deliberately engaged in fire setting with the intention of causing serious damage
**9.** Has deliberately destroyed others' property (other than by fire setting)

Deceitfulness or theft

**10.** Has broken into someone else's house, building, or car
**11.** Often lies to obtain goods or favors or to avoid obligations (i.e., "cons" others)
**12.** Has stolen items of nontrivial value without confronting a victim (e.g., shoplifting, but without breaking and entering; forgery)

Serious violations of rules

**13.** Often stays out at night despite parental prohibitions, beginning before age 13 years
**14.** Has run away from home overnight at least twice while living in parental or parental surrogate home (or once without returning for a lengthy period)
**15.** Is often truant from school, beginning before age 13 years

**B.** The disturbance in behavior causes clinically significant impairment in social, academic, or occupational functioning.

**C.** If the individual is age 18 years or older, criteria are not met for antisocial personality disorder.

Specify type based on age at onset:

Childhood-onset type: Onset of at least one criterion characteristic of conduct disorder prior to age 10 years

Adolescent-onset type: Absence of any criteria characteristic of conduct disorder prior to age 10 years

Specify severity:

Mild: Few if any conduct problems in excess of those required to make the diagnosis and conduct problems cause only minor harm to others

Moderate: Number of conduct problems and effect on others intermediate between "mild" and "severe"

Severe: Many conduct problems in excess of those required to make the diagnosis or conduct problems cause considerable harm to others

*Source:* Reprinted, with permission, from American Psychiatric Association. (2000). *Diagnostic and statistical manual of mental disorders* (4th ed., text revision). Washington, DC: Author, © 2000 American Psychiatric Association.

early stages, this research is refining the search for genes—not for ones that "cause" antisocial personality disorder but for genes that create the unusual aspects of an antisocial personality, such as fearlessness, aggressiveness, impulsivity, and lack of remorse.

### *Neurobiological Influences*

A great deal of research has focused on neurobiological influences that may be specific to antisocial personality disorder. One thing seems clear: General brain damage does not explain why some people become psychopaths or criminals; these individuals appear to score as well on neuropsychological tests as the rest of us (Hart, Forth, & Hare, 1990). However, such tests are designed to detect significant damage in the brain and will not pick up subtle changes in chemistry or structure that could affect behavior.

**Arousal Theories** The fearlessness, seeming insensitivity to punishment, and thrill-seeking behaviors characteristic of those with antisocial personality disorder (especially those with psychopathy) sparked interest in what neurobiological processes might contribute to these unusual reactions. Early theoretical work on people with antisocial personality disorder emphasized two hypotheses: the underarousal hypothesis and the fearlessness hypothesis. According to the *underarousal hypothesis,* psychopaths have abnormally low levels of cortical arousal (Sylvers, Ryan, Alden, & Brennan, 2009). There appears to be an inverted U-shaped relation between arousal and performance. The *Yerkes-Dodson curve* suggests that people with either high or low levels of arousal tend to experience negative affect and perform poorly in many situations, whereas individuals with intermediate levels of arousal tend to be relatively content and perform satisfactorily in most situations.

According to the underarousal hypothesis, the abnormally low levels of cortical arousal characteristic of psychopaths are the primary cause of their antisocial and risk-taking behaviors; they seek stimulation to boost their chronically low levels of arousal. This means that Ryan lied, took drugs, and dug up graves to achieve the same level of arousal we might get from talking on the phone with a good friend or watching television. Several researchers have examined childhood and adolescent psychophysiological predictors of adult antisocial behavior and criminality. Raine, Venables, and Williams (1990), for example, assessed a sample of 15-year-olds on a variety of autonomic and central nervous system variables. They found that future criminals had lower skin conductance activity, lower heart rate during rest periods, and more slow-frequency brain wave activity, all indicative of low arousal.

According to the fearlessness hypothesis, psychopaths possess a higher threshold for experiencing fear than most other individuals (Lykken, 1957, 1982). In other words, things that greatly frighten the rest of us have little effect on the psychopath. Remember that Ryan was unafraid of going alone to dangerous neighborhoods to buy drugs. According to proponents of this hypothesis, the fearlessness of the psychopath gives rise to all the other major features of the syndrome.

▲ Many prisons allow visits between inmates and their children, partly to help reduce later problems in those children.

Theorists have tried to connect what we know about the workings of the brain with clinical observations of people with antisocial personality disorder, especially those with psychopathy. Several theorists have applied Jeffrey Gray's (1987) model of brain functioning to this population (Fowles, 1988; Quay, 1993). According to Gray, three major brain systems influence learning and emotional behavior: the behavioral inhibition system (BIS), the reward system, and the fight/flight system. Two of these systems, the BIS and the reward system, have been used to explain the behavior of people with psychopathy. The BIS is responsible for our ability to stop or slow down when we are faced with impending punishment, nonreward, or novel situations; activation of this system leads to anxiety and frustration. The BIS is thought to be located in the septohippocampal system and involves the noradrenergic and serotonergic neurotransmitter systems. The reward system is responsible for how we behave—in particular, our approach to positive rewards—and is associated with hope and relief. This system probably involves the dopaminergic system in the mesolimbic area of the brain, which we previously noted as the "pleasure pathway" for its role in substance use and abuse (see Chapter 11).

If you think about the behavior of psychopaths, the possible malfunctioning of these systems is clear. An imbalance between the BIS and the reward system may make the fear and anxiety produced by the BIS less apparent and the positive feelings associated with the reward system more prominent (Levenston, Patrick, Bradley, & Lang, 2000; Quay, 1993). Theorists have proposed that this type of neurobiological dysfunction may explain why psychopaths aren't anxious about committing the antisocial acts that characterize their disorder.

Researchers continue to explore how differences in neurotransmitter function (for example, serotonin) and neurohormone function (for example, androgens such as testosterone and the stress neurohormone cortisol) in the brains of these individuals can explain the callousness, superficial charm, lack of remorse, and impulsivity that characterize people with psychopathy. Integrative theories that link these differences to both genetic and environmental influences are just now beginning to be outlined (van Goozen et al., 2007) and may lead to better understanding and treatments for this debilitating disorder.

### Psychological and Social Dimensions

What goes on in the mind of a psychopath? In one of several studies of how psychopaths process reward and punishment, Newman, Patterson, and Kosson (1987) set up a card-playing task on a computer; they provided five-cent rewards and fines for correct and incorrect answers to psychopathic and nonpsychopathic criminal offenders. The game was constructed so that at first players were rewarded about 90% of the time and fined only about 10% of the time. Gradually, the odds changed until the probability of getting a reward was 0%. Despite feedback that reward was no longer forthcoming, the psychopaths continued to play and lose, while those without psychopathy stopped playing. As a result of this and other studies, the researchers hypothesized that once psychopaths set their sights on a reward goal, they are less likely than nonpsychopaths to be deterred despite signs the goal is no longer achievable (Dvorak-Bertscha, Curtin, Rubinstein, & Newman, 2009). Again, considering the reckless and daring behavior of some psychopaths (robbing banks without a mask and getting caught immediately), failure to abandon an unattainable goal fits the overall picture.

Interesting research suggests that this pattern of persisting in the face of failure may not be true for psychopaths from different racial groups. In replicating the type of research just described across samples of Caucasian and African American offenders, Newman and Schmitt (1998) found that the African American offenders did not make the same types of errors as their Caucasian counterparts. One explanation for this difference may be that because African American males are incarcerated at a higher rate than people from other groups, the population in prison may have a lower rate of psychopathy and therefore be less likely to commit such errors (Newman & Schmitt, 1998).

Gerald Patterson's influential work suggests that aggression in children with antisocial personality disorder may escalate, partly as a result of their interactions with their parents (Granic & Patterson, 2006; Patterson, 1982). He found that the parents often give in to the problem behaviors displayed by their children. For example, a boy's parents ask him to make his bed and he refuses. One parent yells at the boy. The boy yells back and becomes abusive. At some point, his interchange becomes so aversive that the parent stops fighting and walks away, thereby ending the fight but also letting the son not make his bed. Giving in to these problems results in short-term gains for both the parent (calm is restored in the house) and the child (he gets what he wants), but it results in continuing problems. The child has learned to continue fighting and not give up, and the parent learns that the only way to "win" is to withdraw all demands. This "coercive family process" combines with other factors, such as parental depression, poor monitoring of their child's activities, and less parental involvement, to help maintain the aggressive behaviors (Chronis et al., 2007; Patterson, DeBaryshe, & Ramsey, 1989).

Although little is known about which environmental factors play a direct role in causing antisocial personality disorder and psychopathy (as opposed to childhood conduct disorders), evidence from adoption studies strongly suggests that shared environmental factors—that tend to make family members similar—are important to the etiology of criminality and perhaps antisocial personality disorder. For example, in the adoption study by Sigvardsson, Cloninger, Bohman, and von-Knorring (1982), low social status of the adoptive parents increased the risk of nonviolent criminality among females. Like children with conduct disorders, individuals with antisocial personality disorder come from homes with inconsistent parental discipline (see, for example, Robins, 1966). It is not known for certain, however, whether inconsistent discipline directly causes antisocial personality disorder; it is conceivable, for example, that parents have a genetic vulnerability to antisocial personality disorder that they pass on to their children but that also causes them to be inadequate parents.

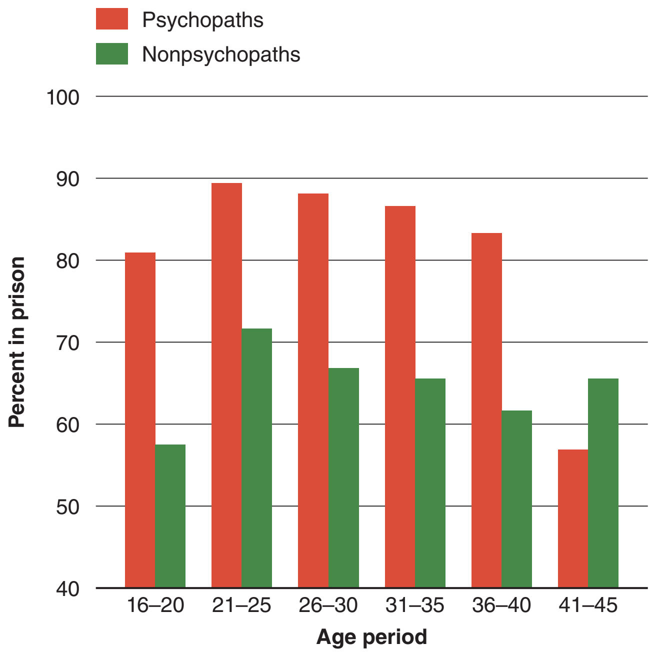
### Developmental Influences

The forms that antisocial behaviors take change as children move into adulthood, from truancy and stealing from friends to extortion, assaults, armed robbery, or other crimes. Fortunately, clinical lore, as well as scattered empirical reports (Robins, 1966), suggest that rates of antisocial behavior begin to decline rather markedly around the age of 40. In their classic study, Hare, McPherson, and Forth (1988) provided empirical support for this phenomenon. They examined the conviction rates of male psychopaths and male nonpsychopaths who had been incarcerated for a variety of crimes. The researchers found that between the ages of 16 and 45 the conviction rates of nonpsychopaths remained relatively constant. In contrast, the conviction rates of psychopaths remained relatively constant up until about 40, at which time they decreased markedly (see ■ Figure 12.3). Why antisocial behavior often declines around middle age remains unanswered.

### An Integrative Model

How can we put all this information together to get a better understanding of people with antisocial personality disorder? Remember that the research just discussed sometimes involved people labeled as having antisocial personality disorder but at other times included people labeled as psychopathic or even criminals. Whatever the label, it appears these people have a genetic vulnerability to antisocial behaviors and personality traits. As you have seen, genetics may lead to differences in neurotransmitter and neurohormone (serotonin and testosterone) function that influences aggressiveness, as well as differences in neurohormone (cortisol) function that affects the way people deal with stress; these brain differences may lead to personality traits such as callousness, impulsivity, and aggressiveness that characterize people with psychopathy (van Goozen et al., 2007).

One potential gene–environment interaction may be seen in the role of fear conditioning in children. If you remember back to Chapter 1 and Chapter 5, we discussed how we learn to fear things that can harm us (for example, a hot stove) through the pairing of an unconditioned stimulus (e.g., heat from burner) and a conditioned stimulus (e.g., parent's warning to stay away), resulting in avoidance of the conditioned stimulus. But what if this conditioning is somehow impaired and you do not learn to avoid things that can harm you? An important study looked at whether abnormal responses to fear conditioning as a young child could be responsible for later antisocial behavior in adults (Gao, Raine, Venables, Dawson, & Mednick, 2010). This large 20-year study assessed fear conditioning in a group of 1,795 children at age 3, and then looked to see who had a criminal record at age 23. They found that offenders showed significantly reduced fear conditioning at age 3 compared to matched comparison participants, with many of these children showing no fear conditioning at all. Deficits in amygdala functioning are thought to make individuals unable to recognize cues that signal threat, making them relatively fearless, which suggests that these children had problems in this area of the brain (Sterzer, 2010). If these findings are replicated, it may point to a mechanism by which genetic influences (leading to damage in the amygdala) interact with environmental influences (learning to fear threats) to produce adults who are relatively fearless and therefore engage in behaviors that cause harm to themselves and others.



■ **FIGURE 12.3** Lifetime course of criminal behavior in psychopaths and nonpsychopaths. (Based on Hare, R. D., McPherson, L. M., & Forth, A. E. (1988). Male psychopaths and their criminal careers. *Journal of Consulting and Clinical Psychology, 56,* 710–714.)

Biological influences further interact with other environmental experiences such as early childhood adversity. In a family that may already be under stress because of divorce or substance abuse, there may be an interaction style that encourages antisocial behavior on the part of the child (Thomas, 2009). The child's antisocial and impulsive behavior—partly caused by the child's difficult temperament and impulsivity (Chronis et al., 2007; Kochanska, Aksan, & Joy, 2007)—alienates other children who might be good role models and attracts others who encourage antisocial behavior. These behaviors may also result in the child dropping out of school and a poor occupational history in adulthood, which help create increasingly frustrating life circumstances that further incite acts against society (Thomas, 2009).

This is, admittedly, an abbreviated version of a complex scenario. The important element is that in this integrative model of antisocial behavior, biological, psychological, and cultural factors combine in intricate ways to create someone like Ryan.

### Treatment

One of the major problems with treating people in this group is typical of numerous personality disorders: They rarely identify themselves as needing treatment. Because of this, and because they can be manipulative even with their therapists, most clinicians are pessimistic about the outcome of treatment for adults who have antisocial personality disorder, and there are few documented success stories (National Collaborating Centre for Mental Health, 2010). In general, therapists agree with incarcerating these people to deter future antisocial acts. Clinicians encourage identification of high-risk children so that treatment can be attempted before they become adults (National Collaborating Centre for Mental Health, 2010; Thomas, 2009).

The most common treatment strategy for children involves parent training (Patterson, 1986; Sanders, 1992). Parents are

▲ Children with conduct disorder may become adults with antisocial personality disorder.

taught to recognize behavior problems early and how to use praise and privileges to reduce problem behavior and encourage prosocial behaviors. Treatment studies typically show that these types of programs can significantly improve the behaviors of many children who display antisocial behaviors (Conduct Problems Prevention Research Group, 2010). A number of factors, however, put families at risk either for not succeeding in treatment or for dropping out early; these include cases with a high degree of family dysfunction, socioeconomic disadvantage, high family stress, a parent's history of antisocial behavior, and severe conduct disorder on the part of the child (Kaminski, Valle, Filene, & Boyle, 2008).

### Prevention

We have seen a dramatic increase in the amount of research on prevention strategies focused on children at risk for later antisocial personality disorder. The aggressive behavior of young children is remarkably stable, meaning that children who hit, insult, and threaten others are likely to continue as they grow older. Unfortunately, these behaviors become more serious over time and are the early signs of the homicides and assaults seen among some adults (Eron & Huesmann, 1990; Singer & Flannery, 2000).

Approaches to change this aggressive course are being implemented mainly in school and preschool settings and emphasize behavioral supports for good behavior and skills training to improve social competence (Reddy, Newman, De Thomas, & Chun, 2009). A number of types of these programs are under evaluation, and the results look promising. For example, research using parent training for young children (toddlers from 1½ to 2½ years) suggests that early intervention may be particularly helpful (Shaw, Dishion, Supplee, Gardner, & Arnds, 2006). Aggression can be reduced and social competence (for example, making friends and sharing) can be improved among young children, and these results generally are maintained over a few years (Conduct Problems Prevention Research, 2010; Reddy et al., 2009). It is too soon to assess the success of such programs in preventing adult antisocial behaviors typically observed among people with this personality disorder. However, given the ineffectiveness of treatment for adults, prevention may be the best approach to this problem.

## Borderline Personality Disorder

People with **borderline personality disorder** lead tumultuous lives. Their moods and relationships are unstable, and usually they have a poor self-image. These people often feel empty and are at great risk of dying by their own hands. Consider the case of Claire.

### **CLAIRE** | *A Stranger Among Us*

I have known Claire for more than 40 years and have watched her through the good but mostly bad times of her often shaky and erratic life as a person with borderline personality disorder. Claire and I went to school together from the eighth grade through high school, and we've kept in touch periodically. My earliest memory of her is of her hair, which was cut short rather unevenly. She told me that when things were not going well she cut her own hair severely, which helped to "fill the void." I later found out that the long sleeves she usually wore hid scars and cuts that she had made herself.

Claire was the first of our friends to smoke. What was unusual about this and her later drug use was not that they occurred (this was in the 1960s when "If it feels good, do it" hadn't been replaced by "Just say no") or that they began early; it was that she didn't seem to use them to get attention, like everyone else. Claire was also one of the first whose parents divorced, and both of them seemed to abandon her emotionally. She later told me that her father was an alcoholic who had regularly beaten her and her mother. She did poorly in school and had a low opinion of herself. She often said she was stupid and ugly, yet she was neither.

Throughout our school years, Claire left town periodically, without any explanation. I learned many years later that she was in psychiatric facilities to get help with her suicidal depression. She often threatened to kill herself, although we didn't guess that she was serious.

In our later teens, we all drifted away from Claire. She had become increasingly unpredictable, sometimes berating us for a perceived slight ("You're walking too fast. You don't want to be seen with me!"), and at other times desperate to be around us. We were confused by her behavior. With some people, emotional outbursts can bring you closer together. Unfortunately for Claire, these incidents and her overall demeanor made us feel that we didn't know her. As we all grew older, the "void" she described in herself became overwhelming and eventually shut us all out.

Claire married twice, and both times had passionate but stormy relationships interrupted by hospitalizations. She tried to stab her first husband during a particularly violent rage. She tried a number of drugs but mainly used alcohol to "deaden the pain."

Now, in her mid-50s, things have calmed down some, although she says she is rarely happy. Claire does feel a little better about herself and is doing well as a travel agent. Although she is seeing someone, she is reluctant to become involved because of her personal history. Claire was ultimately diagnosed with depression and borderline personality disorder.

© Dr. P. Marazzi/SPL/Photo Researchers, Inc.

▲ Borderline personality disorder is often accompanied by self-mutilation.

### Clinical Description

Borderline personality disorder is one of the most common personality disorders observed in clinical settings; it is observed in every culture and is seen in about 1% to 2% of the general population (Cloninger & Svakic, 2009). Claire's life illustrates the instability characteristic of people with borderline personality disorder. They tend to have turbulent relationships, fearing abandonment but lacking control over their emotions (Linehan & Dexter-Mazza, 2008). They often engage in behaviors that are suicidal, self-mutilative, or both, cutting, burning, or punching themselves. Claire sometimes used her cigarette to burn her palm or forearm, and she carved her initials in her arm. A significant proportion—about 6%—succeed at suicide (McGirr, Paris, Lesage, Renaud, & Turecki, 2009). On the positive side, the long-term outcome for people with borderline personality disorder is encouraging, with up to 88% achieving remission more than 10 years after initial treatment (Zanarini et al., 2006).

People with this personality disorder are often intense, going from anger to deep depression in a short time. Dysfunction in the area of emotion is sometimes considered one of the core features of borderline personality disorder (Linehan & Dexter-Mazza, 2008) and is one of the best predictors of suicide in this group (McGirr et al., 2009).

These individuals also are characterized by impulsivity, which can be seen in their drug abuse and self-mutilation. Although not so obvious as to why, the self-injurious behaviors such as cutting sometimes are described as tension reducing by people who engage in these behaviors (Nock, Cha, & Dour, in press). Claire's empty feeling is also common; these people are sometimes described as chronically bored and have difficulties with their own identities (Linehan & Dexter-Mazza, 2008). The mood disorders we discussed in Chapter 7 are common among people with borderline personality disorder, with about 20% having major depression and about 40% having bipolar disorder (Grant et al., 2008). Eating disorders are also common, particularly bulimia (see Chapter 8): Almost 25% of people with bulimia also have borderline personality disorder (Zanarini, Reichman, Frankenburg, Reich, & Fitzmaurice, 2010). Up to 67% of the people with borderline personality disorder are also diagnosed with at least one substance use disorder (Grant et al., 2008). As with antisocial personality disorder, people with borderline personality disorder tend to improve during their 30s and 40s, although they may continue to have difficulties into old age (National Collaborating Centre for Mental Health, 2009).

**DSM-IV-TR** **Table 12.7** Diagnostic Criteria for Borderline Personality Disorder

A pervasive pattern of instability of interpersonal relationships, self-image, and affects, and marked impulsivity beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

1. Frantic efforts to avoid real or imagined abandonment; *note:* do not include suicidal or self-mutilating behavior covered in criterion 5
2. A pattern of unstable and intense interpersonal relationships characterized by alternating between extremes of idealization and devaluation
3. Identity disturbance: Markedly and persistently unstable self-image or sense of self
4. Impulsivity in at least two areas that are potentially self-damaging (e.g., spending, sex, substance abuse, reckless driving, binge eating); *note:* do not include suicidal or self-mutilating behavior covered in criterion 5
5. Recurrent suicidal behavior, gestures, or threats, or self-mutilating behavior
6. Affective instability due to a marked reactivity of mood (e.g., intense episodic dysphoria, irritability, or anxiety usually lasting a few hours and only rarely more than a few days)
7. Chronic feelings of emptiness
8. Inappropriate, intense anger or difficulty controlling anger (e.g., frequent displays of temper, constant anger, recurrent physical fights)
9. Transient, stress-related paranoid ideation or severe dissociative symptoms

### Causes

The results from numerous family studies suggest that borderline personality disorder is more prevalent in families with the disorder and somehow linked with mood disorders (Distel, Trull, & Boomsma, 2009). Studies of monozygotic (identical) and dizygotic (fraternal) twins indicated a higher concordance rate among monozygotic twins, further supporting the role of genetics in the expression of borderline personality disorder (for example, Reichborn-Kjennerud et al., 2009).

The emotional reactivity that is a central aspect of borderline personality disorder has led researchers to look at this personality trait for clues about inherited influences (endophenotypes). Important genetic studies are investigating genes associated with the neurochemical serotonin because dysfunction in this system has been linked to the emotional instability, suicidal behaviors, and impulsivity seen in people with this disorder (Distel et al., 2009). This research is in its early stages and there are as yet no solid answers for how genetic differences lead to the symptoms of borderline personality disorder.

Neuroimaging studies, designed to locate areas in the brain contributing to borderline personality disorder, point to the limbic network (Nunes et al., 2009). Significantly, this area in the brain is involved in emotion regulation and dysfunctional serotonin neurotransmission, linking these findings with genetic research.

To further "zero in" on the nature of this disorder, it is necessary to refine the concept of emotional reactivity in borderline personality disorder. When asked about their experiences, people with this disorder will report greater emotional fluctuations and greater emotional intensity, primarily in negative emotions such as anger and anxiety (Rosenthal et al., 2008). Some research—using "morphing" technology—is looking at how sensitive these individuals are to the emotions of others. One study tested how people with and without borderline personality disorder could correctly identify the emotion of a face that was morphing on screen (changing slowly from a neutral expression to an emotional expression such as anger) and found those with borderline personality disorder were more accurate than controls (Fertuck et al., 2009).

In one study, the emotion "shame" was explored in people with this disorder (Rusch et al., 2007). For example, people were given the following scenario:

> You attend your coworker's housewarming party and you spill red wine on a new cream-colored carpet, but you think no one notices (pg., 317).

Participants are then asked to say which of the following four reactions they would have:

- "You would wish you were anywhere but at the party" (indicating shame proneness)
- "You would stay late to help clean up the stain after the party" (guilt proneness)
- "You think your coworker should have expected some accidents at such a big party" (detachment)
- "You would wonder why your coworker chose to serve red wine with the new light carpet" (externalization) (pg. 317)

This study found that women with borderline personality disorder (no men were included in this study) were more likely to report shame than healthy women and women with social phobia. Importantly, the researchers also found that this elevated tendency to experience shame was associated with low self-esteem, low quality of life, and high levels of anger and hostility (Rusch et al., 2007). Shame has also been found to be related to self-inflicted injury (for example, cutting) in this population (Brown, Linehan, Comtois, Murray, & Chapman, 2009).

Cognitive factors in borderline personality disorder are just beginning to be explored. Here, the questions are, just how do people with this disorder process information, and does this contribute to their difficulties? One study that looked at the thought processes of these individuals asked people with and without borderline personality disorder to look at words projected on a computer screen and try to remember some of the words and try to forget others (Korfine & Hooley, 2000). When the words were not related to the symptoms of borderline personality disorder—for example, "celebrate," "charming," and "collect"—both groups performed equally well. However, when they were presented with words that might be relevant to the disorder—for example, "abandon," "suicidal," and "emptiness"—individuals with borderline personality disorder remembered more of these words despite being instructed to forget them. This preliminary evidence for a memory bias may hold clues to the nature of this disorder and may someday be helpful in designing more effective treatment (Geraerts & McNally, 2008).

An important environmental risk factor in a gene–environment interaction explanation for borderline personality disorder is the possible contribution of early trauma, especially sexual and physical abuse. Numerous studies show that people with this disorder are more likely to report abuse than are healthy individuals or those with other psychiatric conditions (see, for example, Bandelow et al., 2005; Goldman, D'Angelo, DeMaso, & Mezzacappa, 1992; Ogata et al., 1990). Unfortunately, these types of studies (based on recollection and a correlation between the two phenomena) do not tell us directly whether abuse and neglect cause later borderline personality disorder. In an important study, researchers followed 500 children who had documented cases of childhood physical and sexual abuse and neglect and compared them in adulthood with a control group (no history of reported abuse or neglect) (Widom, Czaja, & Paris, 2009). Significantly more abused and neglected children went on to develop borderline personality disorder compared to controls. This finding is particularly significant for girls and women because girls are 2 or 3 times more likely to be sexually abused than boys (Bebbington et al., 2009).

It is clear that a majority of people who receive the diagnosis of borderline personality disorder have suffered terrible abuse or neglect from both parents, sexual abuse, physical abuse by others, or a combination of these (Ball & Links, 2009). For those who have not reported such histories, some workers are examining just how they could develop borderline personality disorder. For example, factors such as temperament (emotional nature, such as being impulsive, irritable, or hypersensitive) or neurological impairments (being exposed prenatally to alcohol or drugs) and how they interact with parental styles may account for some cases of borderline personality disorder (Graybar & Boutilier, 2002).

Borderline personality disorder has been observed among people who have gone through rapid cultural changes. The problems of identity, emptiness, fears of abandonment, and low anxiety threshold have been found in child and adult immigrants (Laxenaire, Ganne-Vevonec, & Streiff, 1982; Skhiri, Annabi, Bi, & Allani, 1982). These observations further support the possibility that prior trauma may, in some individuals, lead to borderline personality disorder.

Remember, however, that a history of childhood trauma, including sexual and physical abuse, occurs in people with other disorders, such as schizoid personality disorder, somatoform disorder (see Chapter 6), panic disorder (see Chapter 5), and dissociative identity disorder (see Chapter 6). In addition, a portion of individuals with borderline personality disorder have no apparent history of such abuse (Cloninger & Svakic, 2009). Although childhood sexual and physical abuse seems to play an important role in the etiology of borderline personality disorder, neither appears to be necessary or sufficient to produce the syndrome.

### An Integrative Model

Although there is no currently accepted integrative model for this disorder, it is tempting to borrow from the work on anxiety disorders to outline a possible view. If you recall from Chapter 5, we describe the "triple vulnerability" theory (Barlow, 2002; Suárez, Bennett, Goldstein, & Barlow, 2008). The first vulnerability (or diathesis) is a generalized biological vulnerability. We can see the genetic vulnerability to emotional reactivity in people with borderline personality disorder and how this affects specific brain function. The second vulnerability is a generalized psychological vulnerability. In the case of people with this personality disorder, they tend to view the world as threatening and to react strongly to real and perceived threats. The third vulnerability is a specific psychological vulnerability, learned from early environmental experiences; this is where early trauma, abuse, or both may advance this sensitivity to threats. When stressed, a person's biological tendency to be overly reactive interacts with the psychological tendency to feel threatened. This may result in the outbursts and suicidal behaviors commonly observed in this group. This preliminary model awaits validation and further research.

### Treatment

In stark contrast to individuals with antisocial personality disorder who rarely acknowledge requiring help, those with borderline personality disorder appear quite distressed and are more likely to seek treatment even than people with anxiety and mood disorders (Ansell, Sanislow, McGlashan, & Grilo, 2007). Reviews of research on the use of medical treatment for people with this disorder suggest that anticonvulsants (such as drugs used for people with epilepsy) and newer antipsychotics may be effective for treating some of the core symptoms of borderline personality disorder, but that antidepressants have limited usefulness (Citrome et al., 2010). Efforts to provide successful treatment are complicated by problems with drug abuse, compliance with treatment, and suicide attempts. As a result, many clinicians are reluctant to work with people who have borderline personality disorder.

One of the most thoroughly researched psychosocial treatments was developed by Marsha Linehan (Linehan et al., 2006; Linehan et al., 1999; Linehan & Dexter-Mazza, 2008). This approach—called **dialectical behavior therapy (DBT)**—involves helping people cope with the stressors that seem to trigger suicidal behaviors. Priority in treatment is first given to those behaviors that may result in harm (suicidal behaviors), then those behaviors that interfere with therapy, and, finally, those that interfere with the patient's quality of life. Weekly individual sessions provide support, and patients are taught how to identify and regulate their emotions. Problem solving is emphasized so that patients can handle difficulties more effectively. In addition, they receive treatment similar to that used for people with PTSD, in which prior traumatic events are reexperienced to help extinguish the fear associated with them (see Chapter 5). In the final stage of therapy, clients learn to trust their own responses rather than depend on the validation of others, sometimes by visualizing themselves not reacting to criticism.

Results from a number of studies suggest that DBT may help reduce suicide attempts, dropouts from treatment, and hospitalizations (Linehan & Dexter-Mazza, 2008; Stanley & Brodsky, 2009). A follow-up of 39 women who received either dialectical behavior therapy or general therapeutic support (called "treatment as usual") for 1 year showed that, during the first 6 months of follow-up, the women in the DBT group were less suicidal, less angry, and better adjusted socially (Linehan & Kehrer, 1993). Another study examined how treating these individuals with DBT in an inpatient setting (a psychiatric hospital) for approximately 5 days would improve their outcomes (Yen, Johnson, Costello, & Simpson, 2009). The participants improved in a number of areas, such as with a reduction in depression, hopelessness, anger expression, and dissociation. A growing body of evidence is now available to document the effectiveness of this approach to aid many individuals with this debilitating disorder (Stanley & Brodsky, 2005).

Probably some of the most intriguing research we describe in this book involves using the techniques in brain imaging to see how psychological treatments influence brain function. One pilot study examined emotional reactions to upsetting photos (for example, pictures of women being attacked) in controls and in women with borderline personality disorder (Schnell & Herpertz, 2007). This study found that among the women who benefited from treatment, arousal (in the amygdala and hippocampus) to the upsetting photos improved over time as a function of treatment. No changes occurred in controls or in women who did not have positive treatment experiences. This type of integrative research holds enormous promise for our understanding of borderline personality disorder and the mechanisms underlying successful treatment.

## Histrionic Personality Disorder

Individuals with **histrionic personality disorder** tend to be overly dramatic and often seem almost to be acting, which is why the term *histrionic,* which means theatrical in manner, is used. Consider the case of Pat.

## Innovative Approaches

### When East Meets West

Dialectical behavior therapy (DBT) as a treatment for borderline personality disorder combines traditional cognitive behavioral therapy techniques with concepts from Eastern spiritual traditions, including Buddhism (Linehan & Dexter-Mazza, 2008). In addition to incorporating treatment techniques we have described for other disorders—including teaching problem-solving skills and cognitive-behavioral therapy—DBT uses aspects of "mindfulness" (the act of directing attention to the experiences occurring in the present moment in a nonjudgmental accepting manner) (Baer & Krietemeyer, 2008). The idea of being mindful has a long tradition in Eastern spiritual practices, and is increasingly being incorporated into a variety of interventions currently being used to address other psychological problems. These problems include stress in survivors of breast cancer (mindfulness-based stress reduction; Lengacher et al., 2009), preventing relapse among people treated for major depression (mindfulness-based cogtive therapy; Mathew, Whitford, Kenny, & Denson, 2010), and reducing an individual's smoking (acceptance and commitment therapy; Bricker, Mann, Marek, Liu, & Peterson, 2010).

One of the advantages in practicing mindfulness is that it encourages embracing your feelings and accepting them in a neutral way. If you recall back to Chapter 5 where we discussed treatments for anxiety-related disorders, you will remember that one of the most important aspects of treating anxiety is exposure to the anxiety-provoking stimuli. So for example, if thoughts about being abandoned by a loved one (which are common in people with borderline personality disorder) make you upset, your natural tendency will be to avoid these thoughts and settings that might trigger them. However, by teaching someone to experience these thoughts in a relaxed manner, and accept them as natural but not dangerous, you increase the chance that the person will be exposed to these stimuli and therefore will have the opportunity to work toward reducing the anxiety surrounding them. We anticipate that many more approaches to helping people with complex problems will begin to incorporate Eastern concepts such as mindfulness as important therapeutic techniques.

### **PAT** *Always Onstage*

When we first met, Pat seemed to radiate enjoyment of life. She was single, in her mid-30s, and was going to night school for her master's degree. She often dressed flamboyantly. During the day she taught children with disabilities, and when she didn't have class she was often out late on a date. When I first spoke with her, she enthusiastically told me how impressed she was with my work in the field of developmental disabilities and that she had been extremely successful in using some of my techniques with her students. She was clearly overdoing the praise, but who wouldn't appreciate such flattering comments?

Because some of our research included children in her classroom, I saw Pat often. Over a period of weeks, however, our interactions grew strained. She often complained of various illnesses and injuries (falling in the parking lot, twisting her neck looking out a window) that interfered with her work. She was disorganized, often leaving to the last minute tasks that required considerable planning. Pat made promises to other people that were impossible to keep but seemed to be aimed at winning their approval; when she broke the promise, she usually made up a story designed to elicit sympathy and compassion. For example, she promised the mother of one of her students that she would put on a "massive and unique" birthday party for her daughter but forgot about it until the mother showed up with cake and juice. Upon seeing her, Pat flew into a rage and blamed the principal for keeping her late after school, although there was no truth to this accusation.

Pat often interrupted meetings about research to talk about her latest boyfriend. The boyfriends changed almost weekly, but her enthusiasm ("Like no other man I have ever met!") and optimism about the future ("He's the guy I want to spend the rest of my life with!") remained high for each of them. Wedding plans were seriously discussed with almost every one, despite their brief acquaintance. Pat was ingratiating, especially to the male teachers, who often helped her out of trouble she got into because of her disorganization.

When it became clear that she would probably lose her teaching job because of her poor performance, Pat managed to manipulate several of the male teachers and the assistant principal into recommending her for a new job in a nearby school district. A year later, she was still at the new school but had been moved twice to different classrooms. According to teachers she worked with, Pat still lacked close interpersonal relationships, although she described her current romantic relationship as "deeply involved." After a rather long period of depression, Pat sought help from a psychologist, who diagnosed her as also having histrionic personality disorder.

### Clinical Description

People with histrionic personality disorder are inclined to express their emotions in an exaggerated fashion, for example, hugging someone they have just met or crying uncontrollably during a sad movie (Skodol & Gunderson, 2008). They also tend to be vain, self-centered, and uncomfortable when they are not in the limelight. They are often seductive in appearance and behavior, and they are typically concerned about their looks. (Pat, for example, spent a great deal of money on unusual jewelry and was sure to point it out to anyone who would listen.) In addition, they seek reassurance and approval constantly and may become upset or angry when others do not attend to them or praise them. People with histrionic personality disorder also tend to be impulsive and have great difficulty delaying gratification.

The cognitive style associated with histrionic personality disorder is impressionistic (Beck, Freeman, & Davis, 2007), characterized by a tendency to view situations in global, black-and-white terms. Speech is often vague, lacking in detail, and characterized by exaggeration (Nestadt et al., 2009). For example, when Pat was asked about a date she had had the night before, she might say it was "way cool" but fail to provide more detailed information.

The high rate of this diagnosis among women versus men raises questions about the nature of the disorder and its diagnostic criteria. As we first discussed in the beginning of this chapter, there is some thought that the features of histrionic personality disorder, such as overdramatization, vanity, seductiveness, and overconcern with physical appearance, are characteristic of the Western "stereotypical female" and may lead to an overdiagnosis among women. Sprock (2000) examined this important question and found some evidence for a bias among psychologists and psychiatrists to associate the diagnosis with women rather than men.

▲ People with histrionic personality disorder tend to be vain, extravagant, and seductive.

**DSM-IV-TR** **Table 12.8** Diagnostic Criteria for Histrionic Personality Disorder

A pervasive pattern of excessive emotionality and attention seeking, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

1. Is uncomfortable in situations in which he or she is not the center of attention
2. Interaction with others is often characterized by inappropriate sexually seductive or provocative behavior
3. Displays rapidly shifting and shallow expression of emotions
4. Consistently uses physical appearance to draw attention to self
5. Has a style of speech that is excessively impressionistic and lacking in detail
6. Shows self-dramatization, theatricality, and exaggerated expression of emotion
7. Is suggestible, i.e., easily influenced by others or circumstances
8. Considers relationships to be more intimate than they actually are

### Causes

Despite its long history, little research has been done on the causes or treatment of histrionic personality disorder. The ancient Greek philosophers believed that many unexplainable problems of women were caused by the uterus (hysteria) migrating within the body (Abse, 1987). As you have seen, however, histrionic personality disorder also occurs among men.

One hypothesis involves a possible relationship with antisocial personality disorder. Evidence suggests that histrionic personality and antisocial personality co-occur more often than chance would account for. Lilienfeld and colleagues (1986), for example, found that roughly two-thirds of people with a histrionic personality also met criteria for antisocial personality disorder. The evidence for this association has led to the suggestion (see, for example, Cloninger, 1978; Lilienfeld, 1992) that histrionic personality and antisocial personality may be sex-typed alternative expressions of the same unidentified underlying condition. Females with the underlying condition may be predisposed to exhibit a predominantly histrionic pattern, whereas males with the underlying condition may be predisposed to exhibit a predominantly antisocial pattern. Whether this association exists remains a controversial issue, however, and further research on this potential relationship is needed (Dolan & Völlm, 2009; Salekin, Rogers, & Sewell, 1997). The overlap of histrionic personality disorder with other personality disorders (for example, borderline, narcissistic, and dependent personality disorders) has caused some to question whether histrionic personality disorder should be reclassified in *DSM-5* to be included under another personality disorder (such as narcissistic personality disorder) (Bakkevig & Karterud, in press).

### Treatment

Although a great deal has been written about ways of helping people with histrionic personality disorder, little research demonstrates success (Cloninger & Svakic, 2009). Some therapists have tried to modify the attention-getting behavior. Kass, Silvers, and Abrams (1972) worked with five women, four of whom had been hospitalized for suicide attempts and all of whom were later diagnosed with histrionic personality disorder. The women were rewarded for appropriate interactions and fined for attention-getting behavior. The therapists noted improvement after an 18-month follow-up, but they did not collect scientific data to confirm their observation.

A large part of therapy for these individuals usually focuses on the problematic interpersonal relationships. They often manipulate others through emotional crises, using charm, sex, seductiveness, or complaining (Beck et al., 2007). People with histrionic personality disorder often need to be shown how the short-term gains derived from this interactional style result in long-term costs, and they need to be taught more appropriate ways of negotiating their wants and needs.

## Narcissistic Personality Disorder

We all know people who think highly of themselves—perhaps exaggerating their real abilities. They consider themselves somehow different from others and deserving of special treatment. In **narcissistic personality disorder**, this tendency is taken to its extreme. In Greek mythology, Narcissus was a youth who spurned the love of Echo, so enamored was he of his own beauty. He spent his days admiring his own image reflected in a pool of water. Psychoanalysts, including Freud, used the term *narcissistic* to describe people who show an exaggerated sense of self-importance and are preoccupied with receiving attention (Cloninger & Svakic, 2009). Consider the case of Willie.

### **WILLIE** | *It's All About Me*

Willie was an office assistant in a small attorney's office. Now in his early 30s, Willie had an extremely poor job history. He never stayed employed at the same place for more than 2 years, and he spent considerable time working through temporary employment agencies. Your first encounter, however, would make you believe that he was extremely competent and that he ran the office. If you entered the waiting room you were greeted by Willie, even though he wasn't the receptionist. He would be extremely solicitous, asking how he could be of assistance, offer you coffee, and ask you to make yourself comfortable in "his" reception area. Willie liked to talk, and any conversation was quickly redirected in a way that kept him the center of attention.

This type of ingratiating manner was welcomed at first but soon annoyed other staff. This was especially true when he referred to the other workers in the office as his staff, even though he was not responsible for supervising any of them. The conversations with visitors and staff often consumed a great deal of his time and the time of other staff, and this was becoming a problem.

He quickly became controlling in his job—a pattern revealed in his other positions as well—eagerly taking charge of duties assigned to others. Unfortunately, he did not complete these tasks well, and this created a great deal of friction.

When confronted with any of these difficulties, Willie would first blame others. Ultimately, however, it would become clear that Willie's self-centeredness and controlling nature were at the root of many of the office inefficiencies. During a disciplinary meeting with all of the law firm's partners, an unusual step, Willie became explosively abusive and blamed them for being out to get him. He insisted that his performance was exceptional at all of his previous positions—something contradicted by his previous employers—and that they were at fault. After calming down, he revealed a previous drinking problem, a history of depression, and multiple family problems, all of which he believed contributed to any difficulties he experienced.

The firm recommended he be seen at a university clinic as a condition of his continued employment, where he was diagnosed with major depression, as well as narcissistic personality disorder. Ultimately, his behavior—including lateness and incomplete work—resulted in his termination. In a revealing turn of events, Willie reapplied for another position at the same firm 2 years later. A mix-up in records failed to reveal his previous termination, but he lasted only 3 days—showing up late to work on his second and third days. He was convinced he could be successful, yet he could not change his behavior to conform to even the minimal standards needed to be successful at work.

### Clinical Description

People with narcissistic personality disorder have an unreasonable sense of self-importance and are so preoccupied with themselves that they lack sensitivity and compassion for other people (Miller, Campbell, & Pilkonis, 2007). They aren't comfortable unless someone is admiring them. Their exaggerated feelings and their fantasies of greatness, called *grandiosity,* create a number of negative attributes. They require and expect a great deal of special attention—the best table in the restaurant, the illegal parking space in front of the movie theater. They also tend to use or exploit others for their own interests and show little empathy. When confronted with other successful people, they can be extremely envious and arrogant. And because they often fail to live up to their own expectations, they are often depressed.

### Causes and Treatment

We start out as infants being self-centered and demanding, which is part of our struggle for survival. However, part of the socialization process involves teaching children empathy and altruism. Some writers, including Kohut (1971, 1977), believe that narcissistic personality disorder arises largely from a profound failure by the parents of modeling empathy early in a child's development. As a consequence, the child remains fixated at a self-centered, grandiose stage of development. In addition, the child (and later the adult) becomes involved in an essentially endless

## DSM-IV-TR Table 12.9 Diagnostic Criteria for Narcissistic Personality Disorder

A pervasive pattern of grandiosity (in fantasy or behavior), need for admiration and lack of empathy, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

1. Has a grandiose sense of self-importance (e.g., exaggerates achievements and talents, expects to be recognized as superior without commensurate achievements)
2. Is preoccupied with fantasies of unlimited success, power, brilliance, beauty, or ideal love
3. Believes that he or she is "special" and unique and can only be understood by, or should associate with, other special or high-status people (or institutions)
4. Requests excessive admiration
5. Has a sense of entitlement, i.e., unreasonable expectations of especially favorable treatment or automatic compliance with his or her expectations
6. Is interpersonally exploitative, i.e., takes advantage of others to achieve his or her own ends
7. Lacks empathy: Is unwilling to recognize or identify with the feelings and needs of others
8. Is often envious of others or believes that others are envious of him or her
9. Shows arrogant, haughty behaviors or attitudes

*Source:* Reprinted, with permission, from American Psychiatric Association. (2000). *Diagnostic and statistical manual of mental disorders* (4th ed., text revision). Washington, DC: Author, © 2000 American Psychiatric Association.

and fruitless search for the ideal person who will meet her unfulfilled empathic needs.

In a sociological view, Christopher Lasch (1978) wrote in his popular book *The Culture of Narcissism* that this personality disorder is increasing in prevalence in most Western societies, primarily as a consequence of large-scale social changes, including greater emphasis on short-term hedonism, individualism, competitiveness, and success. According to Lasch, the "me generation" has produced more than its share of individuals with narcissistic personality disorder. Indeed, reports confirm that narcissistic personality disorder is increasing in prevalence (Huang et al., 2009). However, this apparent rise may be a consequence of increased interest in and research on the disorder.

Research on treatment options is extremely limited in both number of studies and reports of success (Cloninger & Svakic, 2009; Dhawan, Kunik, Oldham, & Coverdale, in press). When therapy is attempted with these individuals, it often focuses on their grandiosity, their hypersensitivity to evaluation, and their lack of empathy toward others (Beck et al., 2007). Cognitive therapy strives to replace their fantasies with a focus on the day-to-day pleasurable experiences that are truly attainable. Coping strategies such as relaxation training are used to help them face and accept criticism. Helping them focus on the feelings of others is also a goal. Because individuals with this disorder are vulnerable to severe depressive episodes, particularly in middle age, treatment is often initiated for the depression. However, it is impossible to draw any conclusions about the impact of such treatment on the actual narcissistic personality disorder.

## Concept Check 12.3

Correctly identify the type of personality disorder described here.

1. Elaine has low self-esteem and usually feels empty unless she does dangerous and exciting things. She is involved in drugs and has casual sexual encounters, even with strangers. She threatens to commit suicide if her boyfriend suggests getting help or if he talks about leaving her. She alternates between passionately loving and hating him, sometimes going from one extreme to the next in a short time. ____________
2. Lance is 17 and has been in trouble with the law for the past 2 years. He lies to his parents, vandalizes buildings in the community, and often fights with others. He shows no remorse for whom he injures or the grief that he causes his ailing parents. ____________
3. Nancy thinks she is the best at everything. She thinks her performance is always excellent, and is extremely critical of anyone else's success. She constantly looks for admiration and reassurance from others. ____________
4. Samantha is known for being overly dramatic. She cries uncontrollably during sad movies and we sometimes think that she is acting. She is vain and self-centered, interrupting many of our class conversations to discuss her personal life.____________

## Cluster C Personality Disorders

People diagnosed with the next three personality disorders we highlight—avoidant, dependent, and obsessive-compulsive—share common features with people who have anxiety disorders. These anxious or fearful personality disorders are described next.

### Avoidant Personality Disorder

As the name suggests, people with **avoidant personality disorder** are extremely sensitive to the opinions of others and therefore avoid most relationships. Their extremely low self-esteem, coupled with a fear of rejection, causes them to be limited in their friendships and dependent on those they feel comfortable with. Consider the case of Jane.

#### JANE | *Not Worth Noticing*

Jane was raised by an alcoholic mother who had borderline personality disorder and who abused her verbally and physically. As a child, she made sense of her mother's abusive treatment by believing that she (Jane) must be an intrinsically unworthy person to be treated so badly. As an adult in her late 20s, Jane still expected to be rejected when others found out that she was inherently unworthy and bad.

Jane was highly self-critical and predicted that she would not be accepted. She thought that people would not like her, that they would see she was a loser, and that she would not have anything to say. She became upset if she perceived that someone in even the most fleeting encounter was reacting negatively or neutrally. If a newspaper vendor failed to smile at her, or a sales clerk was slightly curt, Jane automatically thought it must be because she (Jane) was somehow unworthy or unlikable. She then felt quite sad. Even when she was receiving positive feedback from a friend, she discounted it. As a result, Jane had few friends and certainly no close ones.

(Case and excerpt reprinted, with permission, from Beck, A. T., & Freeman, A., 1990. *Cognitive therapy of personality disorders.* New York: Guilford Press, © 1990 Guilford Press.)

### Clinical Description

Theodore Millon (1981), who initially proposed this diagnosis, notes that it is important to distinguish between individuals who are asocial because they are apathetic, affectively flat, and relatively uninterested in interpersonal relationships (comparable to what *DSM-IV-TR* terms *schizoid personality disorder*) and individuals who are asocial because they are interpersonally anxious and fearful of rejection. It is the latter who fit the criteria of avoidant personality disorder (Millon & Martinez, 1995). These individuals feel chronically rejected by others and are pessimistic about their future.

**DSM-IV-TR** **Table 12.10** Diagnostic Criteria for Avoidant Personality Disorder

A pervasive pattern of social inhibition, feelings of inadequacy, and hypersensitivity to negative evaluation, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:

1. Avoids occupational activities that involve significant interpersonal contact, because of fears of criticism, disapproval, or rejection
2. Is unwilling to get involved with people unless certain of being liked
3. Shows restraint within intimate relationships because of the fear of being shamed or ridiculed
4. Is preoccupied with being criticized or rejected in social situations
5. Is inhibited in new interpersonal situations because of feelings of inadequacy
6. Views self as socially inept, personally unappealing, or inferior to others
7. Is unusually reluctant to take personal risks or to engage in any new activities because they may prove embarrassing

*Source:* Reprinted, with permission, from American Psychiatric Association. (2000). *Diagnostic and statistical manual of mental disorders* (4th ed., text revision). Washington, DC: Author, © 2000 American Psychiatric Association.

### Causes

Some evidence has found that avoidant personality disorder is related to other subschizophrenia-related disorders—occurring more often in relatives of people who have schizophrenia (Fogelson et al., 2007). A number of theories have been proposed that integrate biological and psychosocial influences as the cause of avoidant personality disorder. Millon (1981), for example, suggests that these individuals may be born with a difficult temperament or personality characteristics. As a result, their parents may reject them, or at least not provide them with enough early, uncritical love. This rejection, in turn, may result in low self-esteem and social alienation, conditions that persist into adulthood. Limited support does exist for psychosocial influences in the cause of avoidant personality disorder. For example, Stravynski, Elie, and Franche (1989) questioned a group of people with avoidant personality disorder and a group of control participants about their early treatment by their parents. Those with the disorder remembered their parents as more rejecting, more guilt engendering, and less affectionate than the control group, suggesting parenting may contribute to the development of this disorder. Similarly, Meyer and Carver (2000) found that these individuals were more likely to report childhood experiences of isolation, rejection, and conflict with others.

### Treatment

In contrast to the scarcity of research into most other personality disorders, there are a number of well-controlled studies on approaches to therapy for people with avoidant personality disorder (Beck et al., 2007). Behavioral intervention techniques for anxiety and social skills problems have had some success (for example, Borge et al., 2010). Because the problems experienced by people with avoidant personality disorder resemble those of people with social phobia, many of the same treatments are used for both groups (see Chapter 5). Therapeutic alliance—the collaborative connection between therapist and client—appears to be an important predictor for treatment success in this group (Strauss et al., 2006).

## Dependent Personality Disorder

We all know what it means to be dependent on another person. People with **dependent personality disorder**, however, rely on others to make ordinary decisions as well as important ones, which results in an unreasonable fear of abandonment. Consider the case of Karen.

### KAREN | *Whatever You Say*

Karen was a 45-year-old married woman who was referred for treatment by her physician for problems with panic attacks. During the evaluation, she appeared to be worried, sensitive, and naive. She was easily overcome with emotion and cried on and off throughout the session. She was self-critical at every opportunity throughout the evaluation. For example, when asked how she got along with other people, she reported that "others think I'm dumb and inadequate," although she could give no evidence as to what made her think that. She reported that she didn't like school because "I was dumb" and that she always felt that she was not good enough.

Karen described staying in her first marriage for 10 years, even though "it was hell." Her husband had affairs with many other women and was verbally abusive. She tried to leave him many times but gave in to his repeated requests to return. She was finally able to divorce him, and shortly afterward she met and married her current husband, whom she described as kind, sensitive, and supportive. Karen stated that she preferred to have others make important decisions and agreed with other people to avoid conflict. She worried about being left alone without anyone to take care of her and reported feeling lost without other people's reassurance. She also reported that her feelings were easily hurt, so she worked hard not to do anything that might lead to criticism.

(Case and excerpt reprinted, with permission, from Beck, A. T., & Freeman, A. (1990). *Cognitive therapy of personality disorders.* New York: Guilford Press, © 1990 by Guilford Press.)

**DSM-IV-TR** **Table 12.11** Diagnostic Criteria for Dependent Personality Disorder

A pervasive and excessive need to be taken care of that leads to submissive and clinging behavior and fears of separation, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

1. Has difficulty making everyday decisions without an excessive amount of advice and reassurance from others
2. Needs others to assume responsibility for most major areas of his or her life
3. Has difficulty expressing disagreement with others because of fear of loss of support or approval; *note:* do not include realistic fears of retribution
4. Has difficulty initiating projects or doing things on his or her own (because of a lack of self-confidence in judgment or abilities rather than a lack of motivation or energy)
5. Goes to excessive lengths to obtain nurturance and support from others, to the point of volunteering to do things that are unpleasant
6. Feels uncomfortable or helpless when alone because of exaggerated fears of being unable to care for himself or herself
7. Urgently seeks another relationship as a source of care and support when a close relationship ends
8. Is unrealistically preoccupied with fears of being left to take case of himself or herself

*Source:* Reprinted, with permission, from American Psychiatric Association. (2000). *Diagnostic and statistical manual of mental disorders* (4th ed., text revision). Washington, DC: Author, © 2000 American Psychiatric Association.

### Clinical Description

Individuals with dependent personality disorder sometimes agree with other people when their own opinion differs so as not to be rejected (Cloninger & Svakic, 2009). Their desire to obtain and maintain supportive and nurturant relationships may lead to their other behavioral characteristics, including submissiveness, timidity, and passivity. People with this disorder are similar to those with avoidant personality disorder in their feelings of inadequacy, sensitivity to criticism, and need for reassurance. However, people with avoidant personality disorder respond to these feelings by avoiding relationships, whereas those with dependent personality disorder respond by clinging to relationships (Cloninger & Svakic, 2009).

### Causes and Treatment

We are all born dependent on other people for food, physical protection, and nurturance. Part of the socialization process involves helping us live independently (Bornstein, 1992). It is thought that such disruptions as the early death of a parent or neglect or rejection by caregivers may cause people to grow up fearing abandonment (Stone, 1993). This view comes from work in child development on "attachment," or how children learn to bond with their parents and other people who are important in their lives (Bowlby, 1977). If early bonding is interrupted, individuals may be constantly anxious that they will lose people close to them.

The treatment literature for this disorder is mostly descriptive; little research exists to show whether a particular treatment is effective (Borge et al., 2010; Paris, 2008). On the surface, because of their attentiveness and eagerness to give responsibility for their problems to the therapist, people with dependent personality disorder can appear to be ideal patients. However, their submissiveness negates one of the major goals of therapy, which is to make the person more independent and personally responsible. Therapy therefore progresses gradually as the patient develops confidence in his ability to make decisions independently (Beck et al., 2007). There is a particular need for care that the patient does not become overly dependent on the therapist.

## Obsessive-Compulsive Personality Disorder

People who have **obsessive-compulsive personality disorder** are characterized by a fixation on things being done "the right way." Although many might envy their persistence and dedication, this preoccupation with details prevents them from completing much of anything. Consider the case of Daniel.

### DANIEL | *Getting It Exactly Right*

Each day at exactly 8 A.M., Daniel arrived at his office at the university where he was a graduate student in psychology. On his way, he always stopped at the 7-Eleven for coffee and the *New York Times.* From 8 A.M. to 9:15 A.M., he drank his coffee and read the paper. At 9:15 A.M., he reorganized the files that held the hundreds of papers related to his doctoral dissertation, now several years overdue. From

10 A.M. until noon, he read one of these papers, highlighting relevant passages. Then he took the paper bag that held his lunch (always a peanut butter and jelly sandwich and an apple) and went to the cafeteria to purchase a soda and eat by himself. From 1 P.M. until 5 P.M., he held meetings, organized his desk, made lists of things to do, and entered his references into a new database program on his computer. At home, Daniel had dinner with his wife, then worked on his dissertation until after 11 P.M., although much of the time was spent trying out new features of his home computer.

Daniel was no closer to completing his dissertation than he had been 4.5 years ago. His wife was threatening to leave him because he was equally rigid about everything at home and she didn't want to remain in this limbo of graduate school forever. When Daniel eventually sought help from a therapist for his anxiety over his deteriorating marriage, he was diagnosed as having obsessive-compulsive personality disorder.

### Clinical Description

Like many with this personality disorder, Daniel is work oriented, spending little time going to movies or parties or doing anything that isn't related to his graduate studies. Because of their general rigidity, these people tend to have poor interpersonal relationships (Cloninger & Svakic, 2009).

**DSM-IV-TR** **Table 12.12** Diagnostic Criteria for Obsessive-Compulsive Personality Disorder

A pervasive pattern of preoccupation with orderliness, perfectionism, and mental and interpersonal control, at the expense of flexibility, openness, and efficiency, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:

1. Is preoccupied with details, rules, lists, order, organization, or schedules to the extent that the major point of the activity is lost
2. Shows perfectionism that interferes with task completion (e.g., is unable to complete a project because his or her own overly strict standards are not met)
3. Is excessively devoted to work and productivity to the exclusion of leisure activities and friendships (not accounted for by obvious economic necessity)
4. Is overconscientious, scrupulous, and inflexible about matters of morality, ethics, or values (not accounted for by cultural or religious identification)
5. Is unable to discard worn-out or worthless objects even when they have no sentimental value
6. Is reluctant to delegate tasks or to work with others unless they submit to exactly his or her way of doing things
7. Adopts a miserly spending style toward both self and others; money is viewed as something to be hoarded for future catastrophes
8. Shows rigidity and stubbornness

*Source:* Reprinted, with permission, from American Psychiatric Association. (2000). *Diagnostic and statistical manual of mental disorders* (4th ed., text revision). Washington, DC: Author, © 2000 American Psychiatric Association.

This personality disorder seems to be only distantly related to obsessive-compulsive disorder, one of the anxiety disorders we described in Chapter 5. People like Daniel tend not to have the obsessive thoughts and the compulsive behaviors seen in the like-named obsessive-compulsive disorder. Although people with the anxiety disorder sometimes show characteristics of the personality disorder, they show the characteristics of other personality disorders as well (for example, avoidant, histrionic, or dependent) (Eisen, Mancebo, Chiappone, Pinto, & Rasmussen, 2008).

An intriguing theory suggests that the psychological profiles of many serial killers point to the role of obsessive-compulsive personality disorder. Ferreira (2000) notes that these individuals do not often fit the definition of someone with a severe mental illness—such as schizophrenia—but are "masters of control" in manipulating their victims. Their need to control all aspects of the crime fits the pattern of people with obsessive-compulsive personality disorder, and some combination of this disorder and unfortunate childhood experiences may lead to this disturbing behavior pattern. Obsessive-compulsive personality disorder may also play a role among some sex offenders—in particular, pedophiles. Brain-imaging research on pedophiles suggests that brain functioning in these individuals is similar to those with obsessive-compulsive personality disorder (Schiffer et al., 2007). At the other end of the behavioral spectrum, it is also common to find obsessive-compulsive personality disorder among gifted children, whose quest for perfectionism can be quite debilitating (Nugent, 2000).

### Causes and Treatment

There seems to be a weak genetic contribution to obsessive-compulsive personality disorder (Cloninger & Svakic, 2009). Some people may be predisposed to favor structure in their lives, but to reach the level it did in Daniel may require parental reinforcement of conformity and neatness.

Therapy often attacks the fears that seem to underlie the need for orderliness. These individuals are often afraid that what they do will be inadequate, so they procrastinate and excessively rumi-

©Manchan/Digital Vision/Getty Images

▲ People with obsessive-compulsive personality disorder are preoccupied with doing things "the right way."

nate about important issues and minor details alike. Therapists help the individual relax or use distraction techniques to redirect the compulsive thoughts. This form of cognitive-behavioral therapy—following along the lines of treatment for obsessive-compulsive disorder (see Chapter 5)—appears to be effective for people with this personality disorder (Svartberg et al., 2004).

## Concept Check 12.4

Match the following scenarios with the correct personality disorder.

1. During a therapy session John gets up for a glass of water. Ten minutes later John still is not back. He first had to clean the fountain area and neatly arrange the glasses before pouring his glass of water.____________
2. Whitney is self-critical and claims she is unintelligent and has no skills. She is also afraid to be alone and seeks constant reassurance from her family and friends. She says and does nothing about her cheating husband because she thinks that if she shows any resolve or initiative she will be abandoned and will have to take care of herself.____________
3. Mike has no social life because of his great fear of rejection. He disregards compliments and reacts excessively to criticism, which only feeds his pervasive feelings of inadequacy. Mike takes everything personally. ____________

## On the Spectrum

### Emerging Views of Personality Disorders

We opened the chapter discussing the controversies surrounding the classification of the personality disorders. The great degree of overlap (comorbidity) of the disorders—for example, some people are diagnosed with three or more personality disorders—and the use of categories as opposed to dimensions continue to concern the researchers who study these disorders and the clinicians who care for these individuals (South et al., in press). For example, the organization that we use in the chapter (the three clusters of A, B, and C) is also used by *DSM-IV* but is nothing more than a convenient way for clinicians to remember the disorders and is not based on any scientific evidence (Widiger, 2007). Perhaps the most anticipated change in this field is a radical redefinition of the disorders using dimensions, and we expect that the next version of the *DSM*—*DSM-5*—will introduce this new approach and perhaps make us rethink how we view many of the other disorders we cover in this book (Krueger, Skodol, Livesley, Shrout, & Huang, 2008; Lopez, Compton, Grant, & Breiling, 2008; Widiger & Trull, 2007).

One way to introduce dimensions that is currently being discussed is to rate clients on six broad personality trait domains (negative emotionality, introversion, antagonism, disinhibition, compulsivity, and schizotypy) (American Psychiatric Association, 2010). Each of these domains would include more specific "trait facets." For example, under the domain of "compulsivity" would be the facets of perfectionism, perseveration, rigidity, orderliness, and risk aversion. Clinicians would rate clients on a four-point scale as to the extent that these traits are present (from "very little or not at all" to "extremely descriptive"), therefore providing some indication of the dimensional quality of their difficulties. If and how this classification scheme will ultimately be incorporated into mainstream clinical work remains to be resolved.

# Summary

## An Overview of Personality Disorders

- The personality disorders represent long-standing and ingrained ways of thinking, feeling, and behaving that can cause significant distress. Because people may display two or more of these maladaptive ways of interacting with the world, considerable disagreement remains over how to categorize the personality disorders.
- *DSM-IV-TR* includes 10 personality disorders that are divided into three clusters: Cluster A (odd or eccentric) includes paranoid, schizoid, and schizotypal personality disorders; Cluster B (dramatic, emotional, or erratic) includes antisocial, borderline, histrionic, and narcissistic personality disorders; and Cluster C (anxious or fearful) includes avoidant, dependent, and obsessive-compulsive personality disorders.

## Cluster A Personality Disorders

- People with paranoid personality disorder are excessively mistrustful and suspicious of other people, without any justification. They tend not to confide in others and expect other people to do them harm.
- People with schizoid personality disorder show a pattern of detachment from social relationships and a limited range of emotions in interpersonal situations. They seem aloof, cold, and indifferent to other people.
- People with schizotypal personality disorder are typically socially isolated and behave in ways that would seem unusual to most of us. In addition, they tend to be suspicious and have odd beliefs about the world.

## Cluster B Personality Disorders

- People with antisocial personality disorder have a history of failing to comply with social norms. They perform actions most of us would find unacceptable, such as stealing from friends and family. They also tend to be irresponsible, impulsive, and deceitful.
- In contrast to the *DSM-IV-TR* criteria for antisocial personality, which focus almost entirely on observable behaviors (for example, impulsively and repeatedly changing employment, residence, or sexual partners), the related concept of psychopathy primarily reflects underlying personality traits (for example, self-centeredness or manipulativeness).
- People with borderline personality disorder lack stability in their moods and in their relationships with other people, and they usually have poor self-esteem. These individuals often feel empty and are at great risk of suicide.
- Individuals with histrionic personality disorder tend to be overly dramatic and often appear almost to be acting.
- People with narcissistic personality disorder think highly of themselves—beyond their real abilities. They consider themselves somehow different from others and deserving of special treatment.

## Cluster C Personality Disorders

- People with avoidant personality disorder are extremely sensitive to the opinions of others and therefore avoid social relationships. Their extremely low self-esteem, coupled with a fear of rejection, causes them to reject the attention of others.
- Individuals with dependent personality disorder rely on others to the extent of letting them make everyday decisions, as well as major ones; this results in an unreasonable fear of being abandoned.
- People who have obsessive-compulsive personality disorder are characterized by a fixation on things being done "the right way." This preoccupation with details prevents them from completing much of anything.
- Treating people with personality disorders is often difficult because they usually do not see that their difficulties are a result of the way they relate to others.
- Personality disorders are important for the clinician to consider because they may interfere with efforts to treat more specific problems such as anxiety, depression, or substance abuse. Unfortunately, the presence of one or more personality disorders is associated with a poor treatment outcome and a generally negative prognosis.

# Exploring Personality Disorders

- People with personality disorders think and behave in ways that cause distress to themselves and/or the people who care about them.
- There are three main groups, or clusters, of personality disorders, which usually begin in childhood.

## CLUSTER A

Odd or Eccentric

©Gazelle Technologies/RF

### Schizoid

social isolation

**Causes**

**Psychological Influences**

- Very limited range of emotions
- Apparently cold and unconnected
- Unaffected by praise or criticism

**Biological Influences**

- May be associated with lower density of dopamine receptors

**Social/Cultural Influences**

- Preference for social isolation
- Lack of social skills
- Lack of interest in close relationships, including romantic or sexual

**Treatment**

- Learning value of social relationships
- Social skills training with role playing

### Paranoid

extreme suspicion

**Causes**

**Psychological Influences**

- Thoughts that people are malicious, deceptive, and threatening
- Behavior based on mistaken assumptions about others

**Biological Influences**

- Possible but unclear link with schizophrenia

**Social/Cultural Influences**

- “Outsiders” may be susceptible because of unique experiences (e.g., prisoners, refugees, people with hearing impairments, and the elderly)
- Parents’ early teaching may influence

**Treatment**

- Difficult because of client’s mistrust and suspicion
- Cognitive work to change thoughts
- Low success rate

### Schizotypal

suspicion and odd behavior

**Causes**

**Psychological Influences**

- Unusual beliefs, behavior, or dress
- Suspiciousness
- Believing insignificant events are personally relevant (“ideas of reference”)
- Expressing little emotion
- Symptoms of major depressive disorder

**Biological Influences**

- Genetic vulnerability for schizophrenia but without the biological or environmental stresses present in that disorder

**Social/Cultural Influences**

- Preference for social isolation
- Excessive social anxiety
- Lack of social skills

**Treatment**

- Teaching social skills to reduce isolation and suspicion
- Medication (haloperidol) to reduce ideas of reference, odd communication, and isolation
- Low success rate

## CLUSTER C

Anxious or Fearful

### Dependent

pervasive need to be taken care of

**Causes**

**Psychological Influences**

- Early “loss” of caretaker (death, rejection, or neglect) leads to fear of abandonment
- Timidity and passivity

**Biological Influences**

- Each of us born dependent for protection, food, and nurturance

**Social/Cultural Influences**

- Agreement for the sake of avoiding conflict
- Similar to Avoidant in
  - – inadequacy
  - – sensitivity to criticism
  - – need for reassurance

***BUT***

for those same shared reasons

- Avoidants withdraw
- Dependents cling

**Treatment**

- Very little research
- Appear as ideal clients
- Submissiveness negates independence

## CLUSTER B

Dramatic, Emotional, or Erratic

©Thinkstock/Getty Images

*Note: Cluster B also includes Narcissistic Personality Disorder.*

### Antisocial
violation of others' rights

**Psychological Influences**
- Difficulty learning to avoid punishment
- Indifferent to concerns of others

**Biological Influences**
- Genetic vulnerability combined with environmental influences
- Abnormally low cortical arousal
- High fear threshold

**Causes**

**Social/Cultural Influences**
- Criminality
- Stress/exposure to trauma
- Inconsistent parental discipline
- Socioeconomic disadvantage

**Treatment**
- Seldom successful (incarceration instead)
- Parent training if problems are caught early
- Prevention through preschool programs

### Histrionic
excessively emotional

**Psychological Influences**
- Vain and self-centered
- Easily upset if ignored
- Vague and hyperbolic
- Impulsive; difficulty delaying gratification

**Biological Influences**
- Possible link to antisocial disorder
  - women histrionic/men antisocial

**Causes**

**Social/Cultural Influences**
- Overly dramatic behavior attracts attention
- Seductive
- Approval-seeking

**Treatment**
- Little evidence of success
- Rewards and fines
- Focus on interpersonal relations

### Borderline
tumultuous instability

**Psychological Influences**
- Suicidal
- Erratic moods
- Impulsivity

**Biological Influences**
- Familial link to mood disorders
- Possibly inherited tendencies (impulsivity or volatility)

**Causes**

**Social/Cultural Influences**
- Early trauma, especially sexual/physical abuse
- Rapid cultural changes (immigration) may trigger symptoms

**Treatment**
- Dialectical behavior therapy (DBT) Medication:
  - tricyclic antidepressants
  - minor tranquilizers
  - lithium

### Avoidant
inhibition

**Psychological Influences**
- Low self-esteem
- Fear of rejection, criticism leads to fear of attention
- Extreme sensitivity
- Resembles social phobia

**Biological Influences**
- Innate characteristics may cause rejection

**Causes**

**Social/Cultural Influences**
- Insufficient parental affection

**Treatment**
- Behavioral intervention techniques sometimes successful
  - systematic desensitization
  - behavioral rehearsal
- Improvements usually modest

### Obsessive-compulsive
fixation on details

**Psychological Influences**
- Generally rigid
- Dependent on routines
- Procrastinating

**Biological Influences**
- Distant relation to OCD
- Probable weak genetic role
  - predisposition to structure combined with parental reinforcement

**Causes**

**Social/Cultural Influences**
- Very work-oriented
- Poor interpersonal relationships

**Treatment**
- Little information
- Therapy
  - attack fears behind need
  - relaxation or distraction techniques redirect compulsion to order

### STUDENT LEARNING OUTCOMES*

| | |
|---|---|
| **Demonstrate knowledge and understanding representing appropriate breadth and depth in selected content areas of psychology:** | › Biological bases of behavior and mental processes, including physiology, sensation, perception, comparative, motivation, and emotion (APA SLO 1.2.a (3)) ***(see textbook pages 471–476, 482–489)***<br>› The history of psychology, including the evolution of methods of psychology, its theoretical conflicts, and its sociocultural contexts (APA SLO 1.2.b) ***(see textbook pages 469–470)*** |
| **Use the concepts, language, and major theories of the discipline to account for psychological phenomena.** | › Describe behavior and mental processes empirically, including operational definitions (APA SLO 1.3.a) ***(see textbook pages 469–480)*** |
| **Identify appropriate applications of psychology in solving problems, such as:** | › Origin and treatment of abnormal behavior (APA SLO 4.2.b) ***(see textbook pages 481–497)*** |

---

* Portions of this chapter cover learning outcomes suggested by the American Psychological Association (2007) in their guidelines for the undergraduate psychology major. Chapter coverage of these outcomes is identified above by APA Goal and APA Suggested Learning Outcome (SLO).

## Perspectives on Schizophrenia

A middle-aged man walks the streets of New York City with aluminum foil on the inside of his hat so Martians can't read his mind. A young woman sits in her college classroom and hears the voice of God telling her she is a vile and disgusting person. You try to strike up a conversation with the supermarket bagger, but he stares at you vacantly and will say only one or two words in a flat, toneless voice. Each of these people may have **schizophrenia**, the startling disorder characterized by a broad spectrum of cognitive and emotional dysfunctions including delusions and hallucinations, disorganized speech and behavior, and inappropriate emotions.

Schizophrenia is a complex syndrome that inevitably has a devastating effect on the lives of the person affected and on family members. This disorder can disrupt a person's perception, thought, speech, and movement: almost every aspect of daily functioning. Society often devalues these individuals. For example, people with these severe mental health problems are more likely to be harassed in public as are people without schizophrenia (Tarrier, Khan, Cater, & Picken, 2007). And despite important advances in treatment, complete recovery from schizophrenia is rare. This catastrophic disorder takes a tremendous emotional toll on everyone involved. In addition to the emotional costs, the financial drain is considerable. The annual cost of schizophrenia in the United States is estimated to exceed $60 billion when factors such as family caregiving, lost wages, and treatment are considered (Jablensky, 2009; Wu et al., 2005). Because schizophrenia is so widespread, affecting approximately 1 of every 100 people at some point in their lives, and because its consequences are so severe, research on its causes and treatment has expanded rapidly. Given the attention it has received, you would think the question, "What is schizophrenia?" would by now be answered easily. It is not.

In this chapter, we explore this intriguing disorder and review efforts to determine whether schizophrenia is distinct or a combination of disorders. The search is complicated by the presence of subtypes: different presentations and combinations of symptoms such as hallucinations, delusions, and disorders of speech, emotion, and socialization. After discussing the characteristics of people with schizophrenia, we describe research into its causes and treatment.

### Early Figures in Diagnosing Schizophrenia

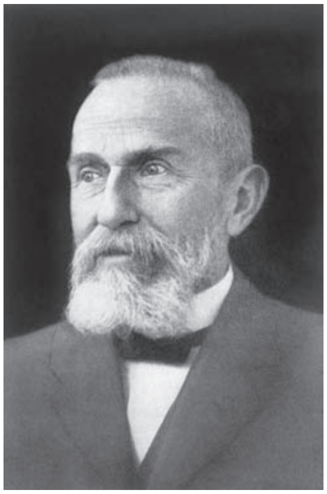
The history of schizophrenia as it has evolved over the years is unparalleled by any other disorder covered in this book. Knowing something about this history will help you understand that the nature of the disorder is multifaceted and treatment is correspondingly complex.

In *Observations on Madness and Melancholy,* published in 1809, John Haslam eloquently portrayed what he called "a form of insanity." In the following passage, Haslam mentions some symptoms that inform our current conception of schizophrenia:

> The attack is almost imperceptible; some months usually elapse before it becomes the subject of particular notice; and fond relatives are frequently deceived by the hope that it is only an abatement of excessive vivacity, conducting to a prudent reserve, and steadiness of character. A degree of apparent thoughtfulness and inactivity precede, together with a diminution of the ordinary curiosity, concerning that which is passing before them; and they therefore neglect those objects and pursuits which formerly proved courses of delight and instruction. The sensibility appears to be considerably blunted: they do not bear the same affection towards their parents and relations: they become unfeeling to kindness, and careless of reproof. . . . I have painfully witnessed this hopeless and degrading change, which in a short time has transformed the most promising and vigorous intellect into a slavering and bloated idiot. (Haslam, 1809/1976, pp. 64–67)

About the same time Haslam was writing his description in England, the French physician Philippe Pinel was writing about people we would describe as having schizophrenia (Pinel, 1801/1962, 1809). Some 50 years later, another physician, Benedict Morel, used the French term *démence* (loss of mind) *précoce* (early, premature), because the onset of the disorder is often during adolescence.

Toward the end of the 19th century, the German psychiatrist Emil Kraepelin (1899) built on the writings of Haslam, Pinel, and Morel (among others) to give us what stands today as the most enduring description and categorization of schizophrenia. Two of Kraepelin's accomplishments are especially important. First, he combined several symptoms of insanity that had usually been viewed as reflecting separate and distinct disorders: **catatonia** (alternating immobility and excited agitation), **hebephrenia** (silly and



▲ Eugen Bleuler (1857–1939), a Swiss psychiatrist, introduced the term *schizophrenia* and was a pioneer in the field.

immature emotionality), and **paranoia** (delusions of grandeur or persecution). Kraepelin thought these symptoms shared similar underlying features and included them under the Latin term **dementia praecox**. Although the clinical manifestation might differ from person to person, Kraepelin believed an early onset at the heart of each disorder develops into "mental weakness."

In a second important contribution, Kraepelin (1898) distinguished dementia praecox from manic-depressive illness (now called bipolar disorder). For people with dementia praecox, an early age of onset and a poor outcome were characteristic; in contrast, these patterns were not essential to manic depression (Lewis, Escalona, & Keith, 2009). Kraepelin also noted the numerous symptoms in people with dementia praecox, including hallucinations, delusions, negativism, and stereotyped behavior.

A second major figure in the history of schizophrenia was Kraepelin's contemporary, Eugen Bleuler (1908), a Swiss psychiatrist who introduced the term *schizophrenia* (Fusar-Poli & Politi, 2008). The label was significant because it signaled Bleuler's departure from Kraepelin on what he thought was the core problem. *Schizophrenia,* which comes from the combination of the Greek words for "split" *(skhizein)* and "mind" *(phren),* reflected Bleuler's belief that underlying all the unusual behaviors shown by people with this disorder was an **associative splitting** of the basic functions of personality. This concept emphasized the "breaking of associative threads," or the destruction of the forces that connect one function to the next. Furthermore, Bleuler believed that a difficulty keeping a consistent train of thought characteristic of all people with this disorder led to the many and diverse symptoms they displayed. Whereas Kraepelin focused on early onset and poor outcomes, Bleuler highlighted what he believed to be the universal underlying problem. Unfortunately, the concept of "split mind" inspired the common but incorrect use of the term *schizophrenia* to mean split or multiple personality. (For a summary of the early contributors to the concept of schizophrenia, see Table 13.1.)

## Identifying Symptoms

It is not easy to point to one thing that makes a person "schizophrenic." As you read about different disorders in this book, you have learned that a particular behavior, way of thinking, or emotion usually defines or is characteristic of each disorder. For example, depression always includes feelings of sadness, and panic disorder is always accompanied by intense feelings of anxiety. Surprisingly, this isn't the case for schizophrenia. Schizophrenia is a number of behaviors or symptoms that aren't necessarily shared by all people who are given this diagnosis. Kraepelin described the situation when he outlined his view of dementia praecox in the late 1800s:

> The complexity of the conditions which we observe in the domain of dementia praecox is very great, so that their inner connection is at first recognizable only by their occurring one after the other in the course of the same disease. In any case certain fundamental disturbances, even though they cannot for the most part be regarded as characteristic, yet return frequently in the same form, but in the most diverse combinations. (Kraepelin, 1919, p. 5)

This mix of symptoms was also highlighted by Bleuler in the title of his 1911 book, *Dementia Praecox or the Group of Schizophrenias,* which emphasizes the complexity of the disorder. The varied nature of schizophrenia is something we come back to throughout this chapter. Individuals who have schizophrenia have varying symptoms, and we find that the causes vary as well.

Despite these complexities, researchers have identified clusters of symptoms that make up the disorder of schizophrenia. Later we describe these dramatic symptoms, such as seeing or hearing things that others do not (hallucinations) or having beliefs that are unrealistic, bizarre, and not shared by others in the same culture (delusions). But first, consider the following case of an individual who had an intense but relatively rare short-term episode of psychotic behavior.

**TABLE 13.1** Early Figures in the History of Schizophrenia

| Date | Historical Figure | Contribution |
|---|---|---|
| 1809 | John Haslam (1764–1844) | Superintendent of a British hospital. In *Observations on Madness and Melancholy,* he outlined a description of the symptoms of schizophrenia. |
| 1801/1809 | Philippe Pinel (1745–1826) | A French physician who described cases of schizophrenia. |
| 1852 | Benedict Morel (1809–1873) | Physician at a French institution who used the term *démence précoce* (in Latin, *dementia praecox*), meaning early or premature *(précoce)* loss of mind *(démence)* to describe schizophrenia. |
| 1898/1899 | Emil Kraepelin (1856–1926) | A German psychiatrist who unified the distinct categories of schizophrenia (hebephrenic, catatonic, and paranoid) under the name *dementia praecox.* |
| 1908 | Eugen Bleuler (1857–1939) | A Swiss psychiatrist who introduced the term *schizophrenia,* meaning splitting of the mind. |

### **ARTHUR** | *Saving the Children*

We first met 22-year-old Arthur at an outpatient clinic in a psychiatric hospital. Arthur's family was extremely concerned and upset by his unusual behavior and was desperately seeking help for him. They said that he was "sick" and "talking like a crazy man," and they were afraid he might harm himself.

Arthur had a normal childhood in a middle-class suburban neighborhood. His parents had been happily married until his father's death several years earlier. Arthur was an average student throughout school and had completed an associate's degree in junior college. His family seemed to think he regretted not continuing on to receive a bachelor's degree. Arthur had worked in a series of temporary jobs, and his mother reported that he seemed satisfied with what he was doing. He lived and worked in a major city, some 15 minutes from his mother and his married brother and sister.

Arthur's family said that about 3 weeks before he came to the clinic he had started speaking strangely. He had been laid off from his job a few days before because of cutbacks and hadn't communicated with any of his family members for several days. When they next spoke with him, his behavior startled them. Although he had always been idealistic and anxious to help other people, he now talked about saving all the starving children in the world with his "secret plan." At first, his family assumed this was just an example of Arthur's sarcastic wit, but his demeanor changed to one of extreme concern and he spoke nonstop about his plans. He began carrying several spiral notebooks that he claimed contained his scheme for helping starving children; he said he would reveal it only at the right time to the right person. Suspecting that Arthur might be taking drugs, which could explain the sudden and dramatic change in his behavior, his family searched his apartment. Although they didn't find any evidence of drug use, they did find his checkbook and noticed a number of strange entries. Over the past several weeks, Arthur's handwriting had deteriorated, and he had written notes instead of the usual check information ("Start to begin now"; "This is important!"; "They must be saved"). He had also made unusual notes in several of his most prized books, a particularly alarming development given his reverence for these books.

As the days went on, Arthur showed dramatic changes in emotion, often crying and acting apprehensive. He stopped wearing socks and underwear and, despite the extremely cold weather, wouldn't wear a jacket when he went outdoors. At the family's insistence, he moved into his mother's apartment. He slept little, and kept the family up until the early morning. His mother said it was like being in a living nightmare. Each morning she would wake up with a knot in her stomach, not wanting to get out of bed because she felt so helpless to do anything to rescue Arthur from his obvious distress.

The family's sense of alarm grew as Arthur revealed more details of his plan. He said that he was going to the German embassy because that was the only place people would listen to him. He would climb the fence at night when everyone was asleep and present his plan to the German ambassador. Fearing that Arthur would be hurt trying to enter the embassy grounds, his family contacted a local psychiatric hospital, described Arthur's condition, and asked that he be admitted. Much to their surprise and disappointment, they were told that Arthur could commit himself but that they couldn't bring him in involuntarily unless he was in danger of doing harm to himself or others. The fear that Arthur might be harmed wasn't sufficient reason to admit him involuntarily.

His family finally talked Arthur into meeting the staff at the outpatient clinic. In our interview, it was clear he was delusional, firmly believing in his ability to help all starving children. After some cajoling, I finally convinced him to let me see his books. He had written random thoughts (for example, "The poor, starving souls"; "The moon is the only place") and made drawings of rocket ships. Parts of his plan involved building a rocket ship that would go to the moon, where he would create a community for all malnourished children, a place where they could live and be helped. After a few brief comments on his plan, I began to ask him about his health.

"You look tired; are you getting enough sleep?"

"Sleep isn't really needed," he noted. "My plans will take me through, and then they can all rest."

"Your family is worried about you," I said. "Do you understand their concern?"

"It's important for all concerned to get together, to join together," he replied.

With that, he got up and walked out of the room and out of the building, after telling his family that he would be right back. After 5 minutes they went to look for him, but he had disappeared. He was missing for 2 days, which caused his family a great deal of concern about his health and safety. In an almost miraculous sequence of events, they found him walking the streets of the city. He acted as if nothing had happened. Gone were his notebooks and the talk of his secret plan.

What caused Arthur to act so strangely? Was it being fired from his job? Was it the death of his father? Was it a genetic predisposition to have schizophrenia or another disorder that kicked in during a period of stress? Unfortunately, we will never know exactly what happened to Arthur to make him behave so bizarrely and then recover so quickly and completely. However, research that we discuss next may shed some light on schizophrenia and potentially help other Arthurs and their families.

## Clinical Description, Symptoms, and Subtypes

The case of Arthur shows the range of problems experienced by people with schizophrenia or other psychotic disorders. The term **psychotic behavior** has been used to characterize many unusual behaviors, although in its strictest sense it usually involves delusions (irrational beliefs) and/or hallucinations (sensory experiences in the absence of external events). Schizophrenia is one of the disorders that involve psychotic behavior; we describe others in more detail later.

Schizophrenia can affect all the functions we rely on each day. Before we describe the symptoms, it is important to look carefully at the specific characteristics of people who exhibit these behaviors, partly because we constantly see distorted images of people with schizophrenia. Headlines such as "Ex-Mental Patient Kills Family" falsely imply that everyone with schizophrenia is dangerous and violent. Popular accounts also contribute to this misinformation. Evidence for violence among people with schizophrenia suggests that although they may be more likely to commit violent acts than the general population, you are more likely to see violence from people with substance abuse problems and personality disorders (antisocial or borderline personality disorders) (Douglas, Guy, & Hart, 2009). Despite this information, more than 70% of characters in prime-time television dramas with schizophrenia are portrayed as violent, with more than one-fifth depicted as murderers (Wahl, 1995). As in mistakenly assuming that *schizophrenia* means "split personality," the popular press misrepresents abnormal psychology to the detriment of people who experience these debilitating disorders.

The fourth edition, text revision, of the *Diagnostic and Statistical Manual (DSM-IV-TR)* has a multiple-part process for determining whether or not someone has schizophrenia. Later we discuss the symptoms the person experiences during the disorder (active phase symptoms), the course of the disorder, and the subtypes of schizophrenia currently in use.

Mental health workers typically distinguish between *positive* and *negative* symptoms of schizophrenia. A third dimension, *disorganized* symptoms, also appears to be an important aspect of the disorder (Lewis et al., 2009). There is not yet universal agreement about which symptoms should be included in these categories. Positive symptoms generally include the more active manifestations of abnormal behavior or an excess or distortion of normal behavior; these include delusions and hallucinations. Negative symptoms involve deficits in normal behavior in such areas as speech and motivation. Disorganized symptoms include rambling speech, erratic behavior, and inappropriate affect (for example, smiling when you are upset). A diagnosis of schizophrenia requires that two or more positive, negative, and/or disorganized symptoms be present for at least 1 month. A great deal of research has focused on the different symptoms of schizophrenia, each of which is described here in some detail.

## DSM-IV-TR **Table 13.1** Diagnostic Criteria for Schizophrenia

**A.** *Characteristic symptoms:* Two (or more) of the following, each present for a significant portion of time during a 1-month period (or less if successfully treated):

1. Delusions
2. Hallucinations
3. Disorganized speech (e.g., frequent derailment or incoherence)
4. Grossly disorganized or catatonic behavior
5. Negative symptoms (i.e., affective flattening, alogia, or avolition)

*Note:* Only one criterion A symptom is required if delusions are bizarre, or hallucinations consist of a voice keeping up a running commentary on the person's behavior or thoughts or two or more voices conversing with each other.

**B.** *Social/occupational dysfunction:* For a significant portion of the time since the onset of the disturbance, one or more major areas of functioning such as work, interpersonal relations, or self-care are markedly below the level achieved prior to the onset (or when the onset is in childhood or adolescence, failure to achieve expected level of interpersonal, academic, or occupational achievement).

**C.** *Duration:* Continuous signs of the disturbance persist for at least 6 months. This 6-month period must include at least 1 month of symptoms (or less if successfully treated) that meet criterion A (i.e., active-phase symptoms) and may include periods of prodromal or residual symptoms. During these prodromal or residual periods, the signs of the disturbance may be manifested by only negative symptoms or two or more symptoms listed in criterion A present in an attenuated form (e.g., odd beliefs, unusual perceptual experiences).

**D.** *Schizoaffective and mood disorder exclusion:* Schizoaffective disorder and mood disorder with psychotic features have been ruled out because either (1) no major depressive, manic, or mixed episodes have occurred concurrently with the active-phase symptoms; or (2) if mood episodes have occurred during active-phase symptoms, their total duration has been brief relative to the duration of the active and residual periods.

**E.** *Substance/general medical condition exclusion:* The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

**F.** *Relationship to a pervasive developmental disorder:* If there is a history of autistic disorder or another pervasive developmental disorder, the additional diagnosis of schizophrenia is made only if prominent delusions or hallucinations are also present for at least a month (or less if successfully treated).

*Classification of longitudinal course* (can be applied only after at least 1 year has elapsed since the initial onset of active-phase symptoms):

Episodic with interepisode residual symptoms (episodes are defined by the reemergence of prominent psychotic symptoms); *also specify if:* with prominent negative symptoms

Episodic with no interepisode residual symptoms

Continuous (prominent psychotic symptoms are present throughout the period of observation); *also specify if:* with prominent negative symptoms

Single episode in partial remission; *also specify if:* with prominent negative symptoms

Single episode in full remission

Other or unspecified pattern

*Source:* Reprinted, with permission, from American Psychiatric Association. (2000). *Diagnostic and statistical manual of mental disorders* (4th ed., text revision). Washington, DC: Author, © 2000 American Psychiatric Association.

## Positive Symptoms

We next describe the **positive symptoms** of schizophrenia, which are the more obvious signs of psychosis. These include the disturbing experiences of delusions and hallucinations. Between 50% and 70% of people with schizophrenia experience hallucinations, delusions, or both (Lindenmayer & Khan, 2006).

### Delusions

A belief that would be seen by most members of a society as a misrepresentation of reality is called a *disorder of thought content,* or a **delusion**. Because of its importance in schizophrenia, delusion has been called "the basic characteristic of madness" (Jaspers, 1963, p. 93). If, for example, you believe that squirrels are aliens sent to Earth on a reconnaissance mission, you would be considered delusional. The media often portray people with schizophrenia as believing they are famous or important people (such as Napoleon or Jesus Christ), although this is only one type of delusion. Arthur's belief that he could end starvation for all the world's children is also a *delusion of grandeur* (a mistaken belief that the person is famous or powerful).

A common delusion in people with schizophrenia is that others are "out to get them." Called *delusions of persecution,* these beliefs can be most disturbing. One of us worked with a world-class cyclist who was on her way to making the Olympic team. Tragically, however, she developed a belief that other competitors were determined to sabotage her efforts, which forced her to stop riding for years. She believed opponents would spray her bicycle with chemicals that would take her strength away, and they would slow her down by putting small pebbles in the road that only she would ride over. These thoughts created a great deal of anxiety, and she refused even to go near her bicycle for some time.

Other more unusual delusions include Capgras syndrome, in which the person believes someone he or she knows has been replaced by a double, and Cotard's syndrome, in which the person believes he is dead (Christodoulou, Margariti, Kontaxakis, & Christodoulou, 2009; Debruyne, Portzky, Van den Eynde, & Audenaert, 2009).

A woman recovering from schizophrenia frankly described her delusional experiences (Weiner, 2003):

> Although my sense of perception remained unaffected, everything I saw and heard took on a halo of meaning that had to be interpreted before I knew how to act. An advertising banner revealed a secret message only I could read. The layout of a store display conveyed a clue. A leaf fell and in its falling spoke: nothing was too small to act as a courier of meaning. For instance, one day I saw a movie poster for "The Net," starring Sandra Bullock. The poster showed Bullock's character in flight from a shadowy organization that had stolen her identity and now threatened her life. Because she had brown eyes and brown hair as I did, I realized she was meant to represent me. Such a warning was alarming. (p. 877)

Why would someone come to believe such obviously improbable things (for example, a friend is replaced by a double or your vote will determine the outcome of a national election)? A number of theories exist and can be summarized into two themes—motivational or deficit theories (McKay, Langdon, & Coltheart, 2007). A *motivational view of delusions* would look at these beliefs as attempts to deal with and relieve anxiety and stress. A person develops "stories" around some issue—for example, a famous person is in love with her (erotomania)—that in a way helps the person make sense out of uncontrollable anxieties in a tumultuous world. Preoccupation with the delusion distracts the individual from the upsetting aspects of the world, such as hallucinations. In contrast, a *deficit view of delusion* sees these beliefs as resulting from brain dysfunction that creates these disordered cognitions or perceptions. Much work remains to develop an integrative account for these intriguing but debilitating symptoms of schizophrenia (McKay & Dennett, 2010).

### Hallucinations

Did you ever think someone called your name, only to discover that no one was there? Did you ever think you saw something move by you, yet nothing did? We all have fleeting moments when we think we see or hear something that isn't there. However, for many people with schizophrenia, these perceptions are real and occur regularly. The experience of sensory events without any input from the surrounding environment is called a **hallucination**. The case of David illustrates the phenomena of hallucinations, as well as other disorders of thought that are common among people with schizophrenia.

### **DAVID** | *Missing Uncle Bill*

David was 25 years old when I met him; he had been living in a psychiatric hospital for about 3 years. He was a little overweight and of average height; he typically dressed in a T-shirt and jeans and tended to be active. I first encountered him while I was talking to another man who lived on the same floor. David interrupted us by pulling on my shoulder. "My Uncle Bill is a good man. He treats me well." Not wanting to be impolite, I said, "I'm sure he is. Maybe after I've finished talking to Michael here, we can talk about your uncle." David persisted, "He can kill fish with a knife. Things can get awfully sharp in your mind, when you go down the river. I could kill you with my bare hands—taking things into my own hands. . . . I know you know!" He was now speaking quickly and had gained emotionality, along with speed, as he spoke. I talked to him quietly until he calmed down for the moment; later, I looked into David's file for some information about his background.

David was brought up on a farm by his Aunt Katie and Uncle Bill. His father's identity is unknown and his mother, who had mental retardation, couldn't care for him. David, too, was diagnosed as having mental retardation, although his functioning was only mildly impaired, and he attended school. The year David's Uncle Bill died, his high school teachers first reported unusual behavior. David occasionally talked to his deceased Uncle Bill in class. Later, he became increasingly agitated and verbally aggressive toward others and was diagnosed as having schizophrenia. He managed to graduate from high school but never obtained a job after that; he lived at home with his aunt for several years. Although his aunt sincerely wanted him to stay with her, his threatening behavior escalated to the point that she requested he be seen at the local psychiatric hospital.

I spoke with David again and had a chance to ask him a few questions. "Why are you here in the hospital, David?" "I really don't want to be here," he told me. "I've got other things to do. The time is right, and you know, when opportunity knocks." He continued for a few minutes until I interrupted him. "I was sorry to hear that your Uncle Bill died a few years ago. How are you feeling about him these days?" "Yes, he died. He was sick and now he's gone. He likes to fish with me, down at the river. He's going to take me hunting. I have guns. I can shoot you and you'd be dead in a minute."

David's conversational speech resembled a ball rolling down a rocky hill. Like an accelerating object, his speech gained momentum the longer he went on and, as if bouncing off obstacles, the topics almost always went in unpredictable directions. If he continued for too long, he often became agitated and spoke of harming others. David also told me that his uncle's voice spoke to him repeatedly. He heard other voices also, but he couldn't identify them or tell me what they said. We return to David's case later in this chapter when we discuss causes and treatments.

Hallucinations can involve any of the senses, although hearing things that aren't there, or *auditory hallucination,* is the most common form experienced by people with schizophrenia. David had frequent auditory hallucinations, usually of his uncle's voice. When David heard a voice that belonged to his Uncle Bill, he often couldn't understand what his uncle was saying; on other occasions, the voice was clearer. "He told me to turn off the TV. He said, 'It's too damn loud, turn it down, turn it down.'" This is consistent with recent views of hallucinations as being related to metacognition or "thinking about thinking." In other words, metacognition is a phrase to describe examining your own thoughts. Most of us have had an occasional intrusive thought that we try not to focus on (for example, thinking "I wish she were dead!" when you know that's not appropriate). People who experience hallucinations appear to have intrusive thoughts, but they believe they are coming from somewhere or someone else (David thinking he is hearing his uncle's voice when it is probably his own thoughts he is "hearing"). They then worry about having these thoughts and engage in meta-worry—or worrying about worrying (Ben-Zeev, Ellington, Swendsen, & Granholm, in press).

Exciting research on hallucinations uses sophisticated brain-imaging techniques to try to localize these phenomena in the brain. Using single photon emission computed tomography (SPECT) to study the cerebral blood flow of men with schizophrenia who also had auditory hallucinations, researchers in London made a surprising discovery (McGuire, Shah, & Murray, 1993). The researchers used the brain-imaging technique while the men were experiencing hallucinations and while they were not, and they found that the part of the brain most active during hallucinations was Broca's area (see ■ Figure 13.1). This is surprising because Broca's area is known to be involved in speech *production,* rather than language *comprehension.* Because auditory hallucinations usually involve understanding the "speech" of others, you might expect more activity in Wernicke's area, which involves language comprehension. However, this study supports an earlier finding by a different group of researchers who also found that Broca's area was more active than Wernicke's area during auditory hallucinations (Cleghorn et al., 1992). These observations support the metacognition theory that people who are hallucinating are *not* hearing the voices of others but are listening to their own thoughts or their own voices and cannot recognize the difference (e.g., Ford et al., 2009).

## Negative Symptoms

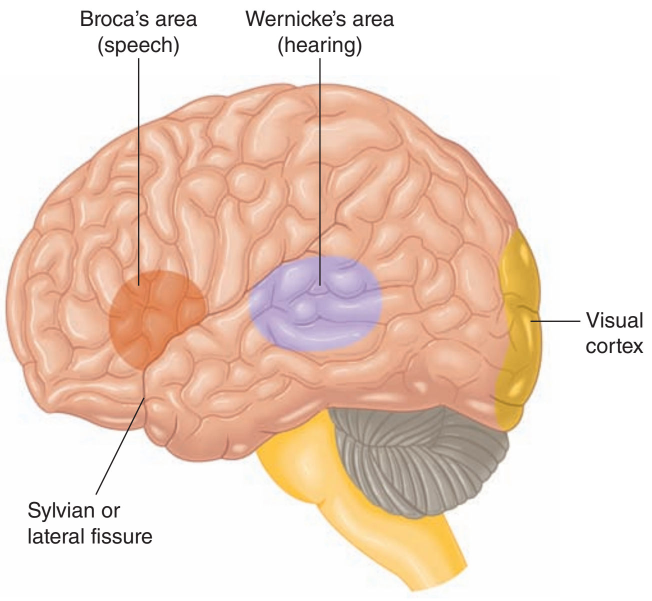
In contrast to the active presentations that characterize the positive symptoms of schizophrenia, the **negative symptoms** usually indicate the absence or insufficiency of normal behavior. They include apathy, poverty of (i.e., limited) thought or speech, and emotional and social withdrawal, and approximately 25% of people with schizophrenia display these symptoms (Lewis et al., 2009).

### Avolition

Combining the prefix *a,* meaning "without," and *volition,* which means "an act of willing, choosing, or deciding," **avolition** is the inability to initiate and persist in activities. People with this symptom (also referred to as *apathy*) show little interest in performing even the most basic day-to-day functions, including those associated with personal hygiene.

### Alogia

Derived from the combination of *a* ("without") and *logos* ("words"), **alogia** refers to the relative absence of speech. A person with alogia may respond to questions with brief replies that



■ **FIGURE 13.1** Major areas of functioning of the cerebral cortex. In most people, only the left hemisphere is specialized for language.

©LWA-Dan Tardif/Corbis

▲ Negative symptoms of schizophrenia include social withdrawal and apathy.

have little content and may appear uninterested in the conversation. For example, to the question, "Do you have any children?" most parents might reply, "Oh yes, I have two beautiful children, a boy and a girl. My son is 6 and my daughter is 12." In the following exchange, someone with alogia responds to the same question:

INTERVIEWER: Do you have any children?
CLIENT: Yes.
I: How many children do you have?
C: Two.
I: How old are they?
C: Six and twelve.

Such deficiency in communication is believed to reflect a negative thought disorder rather than inadequate communication skills. Some researchers, for example, suggest that people with alogia may have trouble finding the right words to formulate their thoughts (Kerns, 2009). Sometimes alogia takes the form of delayed comments or slow responses to questions. Talking with individuals who manifest this symptom can be extremely frustrating, making you feel as if you are "pulling teeth" to get them to respond.

### Anhedonia

A related symptom is called **anhedonia**, which derives from the combination of *a* ("without") and the word *hedonic* ("pertaining to pleasure"). Anhedonia is the presumed lack of pleasure experienced by some people with schizophrenia. Like some mood disorders, anhedonia signals an indifference to activities that would typically be considered pleasurable, including eating, social interactions, and sexual relations.

### Affective Flattening

Imagine that people wore masks at all times: You could communicate with them verbally, but you wouldn't be able to see their emotional reactions. Approximately one-quarter of the people with schizophrenia exhibit what is called **flat affect** (Lewis et al., 2009). They are similar to people wearing masks because they do not show emotions when you would normally expect them to. They may stare at you vacantly, speak in a flat and toneless manner, and seem unaffected by things going on around them. However, although they do not react openly to emotional situations, they may be responding on the inside.

Howard Berenbaum and Thomas Oltmanns (1992) compared people with schizophrenia who had flat (or "blunted") affect with those who did not. The two groups were shown clips from comedies and dramas selected to create emotional reactions in the viewer. Berenbaum and Oltmanns found that the people with flat affect showed little change in facial expression, although they reported experiencing the appropriate emotions. The authors concluded that the flat affect in schizophrenia may represent difficulty expressing emotion, not a lack of feeling. Researchers can now use computer analyses of facial expressions to more objectively assess the emotional expressiveness of people with disorders such as schizophrenia. One such study confirmed the difficulty of people with this disorder to express themselves properly with facial expressions (Alvino et al., 2007). The expression of affect—or the lack of this expression—may be an important symptom of the development of schizophrenia. In a particularly innovative study, researchers videotaped high-risk children (those with one or more parents who had schizophrenia) eating lunch in 1972 and followed them up almost 20 years later (Schiffman et al., 2004). The researchers were able to show that children who later went on to develop schizophrenia typically displayed less positive and more negative affect than those children who did not develop the

### Schizophrenia: Etta

*"If anyone gets into the house, they say I'd get shot. . . . [Who said?] That's the eagle. . . . The eagle works through General Motors. They have something to do with my General Motors check I get every month . . . when you do the 25 of the clock, it means that you leave the house 25 after 1 to mail letters so that they can check on you . . . and they know where you're at. That's the eagle. . . . If you don't do something they tell you to do, Jesus makes the shotgun sound, and then . . . not to answer the phone or the doorbell . . . because you'd get shot [by the] eagle."*

**Go to Psychology CourseMate at www.cengagebrain.com to watch this video.**

disorder. This suggests that emotional expression may be one way to identify potential schizophrenia in children.

## Disorganized Symptoms

Perhaps the least studied and therefore the least understood symptoms of schizophrenia are referred to as the "disorganized symptoms." These include a variety of erratic behaviors that affect speech, motor behavior, and emotional reactions. The prevalence of these behaviors among those with schizophrenia is unclear.

### Disorganized Speech

A conversation with someone who has schizophrenia can be particularly frustrating. If you want to understand what is bothering or upsetting this person, eliciting relevant information is especially difficult. For one thing, people with schizophrenia often lack *insight,* an awareness that they have a problem. In addition, they experience what Bleuler called "associative splitting" and what researcher Paul Meehl called "cognitive slippage" (Bleuler, 1908; Meehl, 1962). These phrases help describe the speech problems of people with schizophrenia: Sometimes they jump from topic to topic, and at other times they talk illogically. *DSM-IV-TR* uses the term **disorganized speech** to describe such communication problems. Let's go back to our conversation with David to demonstrate the symptom.

THERAPIST: Why are you here in the hospital, David?
DAVID: I really don't want to be here. I've got other things to do. The time is right, and you know, when opportunity knocks . . .

David didn't really answer the question he was asked. This type of response is called *tangentiality*—that is, going off on a tangent instead of answering a specific question. David also abruptly changed the topic of conversation to unrelated areas, a behavior that has variously been called *loose association* or *derailment* (Barrera, McKenna, & Berrios, 2009).

THERAPIST: I was sorry to hear that your Uncle Bill died a few years ago. How are you feeling about him these days?
DAVID: Yes, he died. He was sick, and now he's gone. He likes to fish with me, down at the river. He's going to take me hunting. I have guns. I can shoot you and you'd be dead in a minute.

Again, David didn't answer the question. It was unclear whether he didn't understand the question, couldn't focus his attention, or found it too difficult to talk about his uncle. You can see why people spend a great deal of time trying to interpret all the hidden meanings behind this type of conversation. Unfortunately, however, such analyses have yet to provide us with useful information about the nature of schizophrenia or its treatment.

### Inappropriate Affect and Disorganized Behavior

Occasionally, people with schizophrenia display **inappropriate affect**, laughing or crying at improper times. Sometimes they exhibit bizarre behaviors such as hoarding objects or acting in unusual ways in public. People with schizophrenia engage in a number of other "active" behaviors that are usually viewed as unusual. For example, catatonia is one of the most curious symptoms in some individuals with schizophrenia; it involves motor dysfunctions that range from wild agitation to immobility. On the active side of the continuum, some people pace excitedly or move their fingers or arms in stereotyped ways. At the other end of the extreme, people hold unusual postures, as if they were fearful of something terrible happening if they move (**catatonic immobility**). This manifestation can also involve *waxy flexibility,* or the tendency to keep their bodies and limbs in the position they are put in by someone else.

Again, to receive a diagnosis of schizophrenia, a person must display two or more positive, negative, and/or disorganized symptoms for a major portion of at least 1 month. Depending on the combination of symptoms displayed, two people could receive the same diagnosis but behave differently, for example, one having marked hallucinations and delusions and the other displaying disorganized speech and some negative symptoms. Proper treatment depends on differentiating individuals in terms of their varying symptoms.

## Schizophrenia Subtypes

As we noted earlier, the search for subtypes of schizophrenia began before Kraepelin described his concept of schizophrenia. Three divisions have persisted: paranoid (delusions of grandeur or persecution), disorganized (or hebephrenic; silly and immature emotionality), and catatonic (alternate immobility and excited agitation). Although these categories continue to be used in *DSM-IV-TR,* their usefulness is in question. We will discuss in the "On the Spectrum" section at the end of the chapter that they may not be included in *DSM-5* (American Psychiatric Association, 2010). And, as research advances on the underlying biological influences (endophenotypes) of this disorder, it is not clear that they will match these subtypes. In addition, a person's diagnosis can sometimes change over the course of his or her illness; so people can move from one category to another (Lewis et al., 2009). However, we describe the schizophrenia subtypes next for their historic value and because the current diagnostic system relies on these distinctions.

### Paranoid Type

People with the **paranoid type of schizophrenia** stand out because of their delusions or hallucinations; at the same time, their cognitive skills and affect are relatively intact. They generally do not have disorganized speech or flat affect, and they typically have a better prognosis than people with other forms of schizophrenia. The delusions and hallucinations usually have a theme, such as grandeur or persecution. The *DSM-IV-TR* criteria for inclusion in this subtype specify preoccupation with one or more delusions or frequent auditory hallucinations but without a marked display of disorganized speech, disorganized or catatonic behavior, or flat or inappropriate affect (American Psychiatric Association, 2000c).

### Disorganized Type

In contrast to the paranoid type of schizophrenia, people with the **disorganized type of schizophrenia** show marked disruption in their speech and behavior; they also show flat or inappropriate affect, such as laughing in a silly way at the wrong times (American Psychiatric Association, 2000c). They also seem unusually self-absorbed and may spend considerable amounts of time look-

▲ Homeless people who suffer from paranoid schizophrenia often bear the additional burden of persecutory delusions, which interfere with outside efforts to help.

ing at themselves in the mirror (Lewis et al., 2009). If delusions or hallucinations are present, they tend not to be organized around a central theme, as in the paranoid type, but are more fragmented. This subtype was previously called *hebephrenic*. Individuals with this diagnosis tend to show signs of difficulty early, and their problems are often chronic, lacking the remissions (improvement of symptoms) that characterize other forms of the disorder (Lindenmayer & Khan, 2006).

**DSM-IV-TR** **Table 13.2** Diagnostic Criteria for Paranoid Type

A type of schizophrenia in which the following criteria are met:

**A.** Preoccupation with one or more delusions or frequent auditory hallucinations.

**B.** None of the following is prominent: disorganized speech, disorganized or catatonic behavior, or flat or inappropriate affect.

*Source:* Reprinted, with permission, from American Psychiatric Association. (2000). *Diagnostic and statistical manual of mental disorders* (4th ed., text revision). Washington, DC: Author, © 2000 American Psychiatric Association.

**DSM-IV-TR** **Table 13.3** Diagnostic Criteria for Disorganized Type

A type of schizophrenia in which the following criteria are met:

**A.** All the following are prominent:
  **1.** Disorganized speech
  **2.** Disorganized behavior
  **3.** Flat or inappropriate affect

**B.** The criteria are not met for catatonic type.

*Source:* Reprinted, with permission, from American Psychiatric Association. (2000). *Diagnostic and statistical manual of mental disorders* (4th ed., text revision). Washington, DC: Author, © 2000 American Psychiatric Association.

### Catatonic Type

In addition to the unusual motor responses of remaining in fixed positions (called "waxy flexibility" because their limbs and body position can be moved by others) and engaging in excessive activity, individuals with the **catatonic type of schizophrenia** sometimes display odd mannerisms with their bodies and faces, including grimacing (American Psychiatric Association, 2000c). They sometimes repeat or mimic the words of others *(echolalia)* or the movements of others *(echopraxia)*. There may be subtypes of catatonic schizophrenia, with some individuals showing primarily symptoms of labeled "negative withdrawal" (immobility, posturing, mutism), "automatic" (routine obedience, waxy flexibility), "repetitive/echo" (grimacing, perseveration, echolalia), and "agitated/resistive" (excitement, impulsivity, combativeness) (Ungvari, Goggins, Leung, & Gerevich, 2007).

### Undifferentiated Type

People who do not fit neatly into these subtypes are classified as having an **undifferentiated type of schizophrenia**; they include people who have the major symptoms of schizophrenia but who do not meet the criteria for paranoid, disorganized, or catatonic types.

### Residual Type

People who have had at least one episode of schizophrenia but who no longer manifest major symptoms are diagnosed as having the **residual type of schizophrenia**. Although they may not suffer from bizarre delusions or hallucinations, they may display residual or "leftover" symptoms, such as negative beliefs, or they may still have unusual ideas that are not fully delusional. Residual symptoms can include social withdrawal, bizarre thoughts, inactivity, and flat affect. All versions of the *DSM* (from *DSM-I* through *DSM-IV-TR*) have included a residual type to describe the condition of individuals who have less severe problems associated with an episode of schizophrenia.

Research suggests that the paranoid subtype may have a stronger familial link than the others and that these people may function better before and after episodes of schizophrenia than people diagnosed with other subtypes (Lewis et al., 2009). More work will determine whether dividing schizophrenia into five subtypes helps us understand and treat people. Several other disorders also characterized by psychotic behaviors such as hallucinations and delusions do not manifest in the same way as schizophrenia. In

**DSM-IV-TR** **Table 13.4** Diagnostic Criteria for Catatonic Type

A type of schizophrenia in which the clinical picture is dominated by at least two of the following:

1. Motoric immobility as evidenced by catalepsy (including waxy flexibility) or stupor
2. Excessive motor activity (that is apparently purposeless and not influenced by external stimuli)
3. Extreme negativism (an apparently motiveless resistance to all instructions or maintenance of a rigid posture against attempts to be moved) or mutism
4. Peculiarities of voluntary movement as evidenced by posturing (voluntary assumption of inappropriate or bizarre postures), stereotyped movements, prominent mannerisms, or prominent grimacing
5. Echolalia or echopraxia

*Source:* Reprinted, with permission, from American Psychiatric Association. (2000). *Diagnostic and statistical manual of mental disorders* (4th ed., text revision). Washington, DC: Author, © 2000 American Psychiatric Association.

the next section, we first distinguish them from schizophrenia and then describe them in greater detail.

## Other Psychotic Disorders

The psychotic behaviors of some individuals do not fit neatly under the heading of schizophrenia as we have just described. Several other categories of disorders depict these significant variations.

### Schizophreniform Disorder

Some people experience the symptoms of schizophrenia for a few months only; they can usually resume normal lives. The symptoms sometimes disappear as the result of successful treatment, but they often do so for reasons unknown. The label **schizophreniform disorder** classifies these symptoms, but because relatively few studies are available on this disorder, data on important aspects of it are sparse. It appears, however, that the lifetime prevalence is approximately 0.2% (American Psychiatric Association, 2000c). The *DSM-IV-TR* diagnostic criteria for schizophreniform disorder include onset of psychotic symptoms within 4 weeks of the first noticeable change in usual behavior, confusion at the height of the psychotic episode, good *premorbid* (before the psychotic episode) social and occupational functioning (functioning before the psychotic episode), and the absence of blunted or flat affect (Kendler & Walsh, 2007).

**DSM-IV-TR** **Table 13.5** Diagnostic Criteria for Residual Type

A type of schizophrenia in which the following criteria are met:

**A.** Absence of prominent delusions, hallucinations, disorganized speech, and grossly disorganized or catatonic behavior.

**B.** There is continuing evidence of the disturbance, as indicated by the presence of negative symptoms or two or more symptoms listed in criterion A for schizophrenia, present in an attenuated form (e.g., odd beliefs, unusual perceptual experiences).

*Source:* Reprinted, with permission, from American Psychiatric Association. (2000). *Diagnostic and statistical manual of mental disorders* (4th ed., text revision). Washington, DC: Author, © 2000 American Psychiatric Association.

**DSM-IV-TR** **Table 13.6** Diagnostic Criteria for Schizophreniform Disorder

**A.** Criteria A, D, and E of schizophrenia are met.

**B.** An episode of the disorder (including prodromal, active, and residual phases) lasts at least 1 month but less than 6 months. (When the diagnosis must be made without waiting for recovery, it should be qualified as "provisional.")

Specify if:

Without good prognostic features

With good prognostic features: As evidenced by two (or more) of the following:

1. Onset of prominent psychotic symptoms within 4 weeks of the first noticeable change in usual behavior or functioning
2. Confusion or perplexity at the height of the psychotic episode
3. Good premorbid social and occupational functioning
4. Absence of blunted or flat affect

*Source:* Reprinted, with permission, from American Psychiatric Association. (2000). *Diagnostic and statistical manual of mental disorders* (4th ed., text revision). Washington, DC: Author, © 2000 American Psychiatric Association.

### Schizoaffective Disorder

Historically, people who had symptoms of schizophrenia and who exhibited the characteristics of mood disorders (for example, depression or bipolar disorder) were lumped in the category of schizophrenia. Now, however, this mixed bag of problems is diagnosed as **schizoaffective disorder** (Sikich, 2009). The prognosis is similar to the prognosis for people with schizophrenia—that

**DSM-IV-TR** **Table 13.7** Diagnostic Criteria for Schizoaffective Disorder

**A.** An uninterrupted period of illness during which, at some time, there is either a major depressive episode, a manic episode, or a mixed episode concurrent with symptoms that meet criterion a for schizophrenia.

*Note:* The major depressive episode must include criterion A1: depressed mood.

**B.** During the same period of illness, there have been delusions or hallucinations for at least 2 weeks in the absence of prominent mood symptoms.

**C.** Symptoms that meet criteria for a mood episode are present for a substantial portion of the total duration of the active and residual periods of the illness.

**D.** The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

Specify type:

Bipolar type: If the disturbance includes a manic or a mixed episode (or a manic or a mixed episode and major depressive episodes)

Depressive type: If the disturbance only includes major depressive episodes

*Source:* Reprinted, with permission, from American Psychiatric Association. (2000). *Diagnostic and statistical manual of mental disorders* (4th ed., text revision). Washington, DC: Author, © 2000 American Psychiatric Association.

### DSM-IV-TR **Table 13.8** Diagnostic Criteria for Delusional Disorder

**A.** Nonbizarre delusions (i.e., involving situations that occur in real life, such as being followed, poisoned, infected, loved at a distance, or deceived by spouse or lover, or having a disease) of at least 1 month's duration.

**B.** Criterion A for schizophrenia has never been met. *Note:* Tactile and olfactory hallucinations may be present in delusional disorder if they are related to the delusional theme.

**C.** Apart from the impact of the delusion(s) or its ramifications, functioning is not markedly impaired and behavior is not obviously odd or bizarre.

**D.** If mood episodes have occurred concurrently with delusions, their total duration has been brief relative to the duration of the delusional periods.

**E.** The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

Specify type (the following types are assigned based on the predominant delusional theme):

Erotomanic type: Delusions that another person, usually of higher status, is in love with the individual

Grandiose type: Delusions of inflated worth, power, knowledge, identity, or special relationship to a deity or famous person

Jealous type: Delusions that the individual's sexual partner is unfaithful

Persecutory type: Delusions that the person (or someone to whom the person is close) is being malevolently treated in some way

Somatic type: Delusions that the person has some physical defect or general medical condition

Mixed type: Delusions characteristic of more than one of the above types but no one theme predominates

Unspecified type

*Source:* Reprinted, with permission, from American Psychiatric Association. (2000). *Diagnostic and statistical manual of mental disorders* (4th ed., text revision). Washington, DC: Author, © 2000 American Psychiatric Association.

is, individuals tend not to get better on their own and are likely to continue experiencing major life difficulties for many years. *DSM-IV-TR* criteria for schizoaffective disorder require, in addition to the presence of a mood disorder, delusions or hallucinations for at least 2 weeks in the absence of prominent mood symptoms (American Psychiatric Association, 2000c).

## Delusional Disorder

Delusions are beliefs that are not generally held by other members of a society. The major feature of **delusional disorder** is a persistent belief that is contrary to reality, in the absence of other characteristics of schizophrenia. For example, a woman who believes without any evidence that coworkers are tormenting her by putting poison in her food and spraying her apartment with harmful gases has a delusional disorder. This disorder is characterized by a persistent delusion that is not the result of an organic factor such as brain seizures or of any severe psychosis. Individuals with delusional disorder tend not to have flat affect, anhedonia, or other negative symptoms of schizophrenia; importantly, however, they may become socially isolated because they are suspicious of others. The delusions are often long-standing, sometimes persisting over several years (Suvisaari et al., 2009).

*DSM-IV-TR* recognizes the following delusional subtypes: erotomanic, grandiose, jealous, persecutory, and somatic. An *erotomanic type* of delusion is the irrational belief that one is loved by another person, usually of higher status. Some individuals who stalk celebrities appear to have erotomanic delusional disorder. The *grandiose type* of delusion involves believing in one's inflated worth, power, knowledge, identity, or special relationship to a deity or famous person. A person with the *jealous type* of delusion believes the sexual partner is unfaithful. The *persecutory type* of delusion involves believing oneself (or someone close) is being malevolently treated in some way. Finally, with the *somatic delusions* the person feels afflicted by a physical defect or general medical condition. These delusions differ from the more bizarre types often found in people with schizophrenia because in delusional disorder *the imagined events could be happening but aren't* (for example, mistakenly believing you are being followed); in schizophrenia, however, *the imagined events aren't possible* (for example, believing your brain waves broadcast your thoughts to other people around the world).

Delusional disorder seems to be relatively rare, affecting 24 to 30 people out of every 100,000 in the general population (Suvisaari et al., 2009). Among those people with psychotic disorders in general, between 2% and 8% are thought to have delusional disorder (Vahia & Cohen, 2009). Researchers can't be confident about the percentages because they know that many of these individuals have no contact with the mental health system.

The onset of delusional disorder is relatively late: The average age of first admission to a psychiatric facility is between 40 and 49 (Vahia & Cohen, 2009). However, because many people with this disorder can lead relatively normal lives, they may not seek treatment until their symptoms become most disruptive. Delusional disorder seems to afflict more females than males (55% and 45%, respectively, of the affected population).

In a longitudinal study, Opjordsmoen (1989) followed 53 people with delusional disorder for an average of 30 years and found they tended to fare better in life than people with schizophrenia but not as well as those with some other psychotic disorders, such as schizoaffective disorder. About 80% of the 53 individuals had been married at some time, and half were employed, which demonstrates an ability to function relatively well despite delusions.

We know relatively little about either the biological or the psychosocial influences on delusional disorder (Vahia & Cohen, 2009). Research on families suggests that the characteristics of suspiciousness, jealousy, and secretiveness may occur more often among the relatives of people with delusional disorder than among the population at large, suggesting some aspect of this disorder may be inherited (Kendler & Walsh, 2007).

A number of other disorders can cause delusions, and their presence should be ruled out before diagnosing delusional disorder. For example, abuse of amphetamines, alcohol, and cocaine can cause delusions, as can brain tumors, Huntington's disease, and Alzheimer's disease (Vahia & Cohen, 2009).

## Brief Psychotic Disorder

Recall the puzzling case of Arthur, who suddenly experienced the delusion that he could save the world and whose intense emotional swings lasted for only a few days. He would receive the *DSM-IV-TR* diagnosis of **brief psychotic disorder**, which is characterized by the presence of one or more positive symptoms such as delusions,

### DSM-IV-TR Table 13.9 Diagnostic Criteria for Brief Psychotic Disorder

**A.** Presence of one (or more) of the following symptoms:
   **1.** Delusions
   **2.** Hallucinations
   **3.** Disorganized speech (e.g., frequent derailment or incoherence)
   **4.** Grossly disorganized or catatonic behavior

*Note:* Do not include a symptom if it is a culturally sanctioned response pattern.

**B.** Duration of an episode of the disturbance is at least 1 day but less than 1 month, with eventual full return to premorbid level of functioning.

**C.** The disturbance is not better accounted for by a mood disorder with psychotic features, schizoaffective disorder, or schizophrenia and is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

Specify if:

With marked stressor(s) (brief reactive psychosis): If symptoms occur shortly after and apparently in response to events that, singly or together, would be markedly stressful to almost anyone in similar circumstances in the person's culture

Without marked stressor(s): If psychotic symptoms do *not* occur shortly after, or are not apparently in response to events that, singly or together, would be markedly stressful to almost anyone in similar circumstances in the person's culture

With postpartum onset: If onset within 4 weeks postpartum

*Source:* Reprinted, with permission, from American Psychiatric Association. (2000). *Diagnostic and statistical manual of mental disorders* (4th ed., text revision). Washington, DC: Author, © 2000 American Psychiatric Association.

hallucinations, or disorganized speech or behavior lasting 1 month or less. Individuals like Arthur regain their previous ability to function well in day-to-day activities. Brief psychotic disorder is often precipitated by extremely stressful situations.

### *Shared Psychotic Disorder (Folie à Deux)*

Relatively little is known about **shared psychotic disorder (folie à deux)**, the condition in which an individual develops delusions simply as a result of a close relationship with a delusional individual. The content and nature of the delusion originate with the partner and can range from the relatively bizarre, such as believing enemies are sending harmful gamma rays through your house, to the fairly ordinary, such as believing you are about to receive a major promotion despite evidence to the contrary. Although it was once thought that this disorder was more common among mother–daughter or sister–sister pairs, this does not appear to be the case (Shimizu, Kubota, Toichi, & Baba, 2007).

**Schizotypal personality disorder,** discussed in Chapter 12, is a related psychotic disorder. As you may recall, the characteristics are similar to those experienced by people with schizophrenia but are less severe. Some evidence also suggests that schizophrenia and schizotypal personality disorder may be genetically related as part of a "schizophrenia spectrum."

Remember that although people with related psychotic disorders display many of the characteristics of schizophrenia, these disorders differ significantly.

### DSM-IV-TR Table 13.10 Diagnostic Criteria for Shared Psychotic Disorder

**A.** A delusion develops in an individual in the context of a close relationship with another person(s), who has an already-established delusion.

**B.** The delusion is similar in content to that of the person who already has the established delusion.

**C.** The disturbance is not better accounted for by another psychotic disorder (e.g., schizophrenia) or a mood disorder with psychotic features and is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

*Source:* Reprinted, with permission, from American Psychiatric Association. (2000). *Diagnostic and statistical manual of mental disorders* (4th ed., text revision). Washington, DC: Author, © 2000 American Psychiatric Association.

## Concept Check 13.1

### Part A

Determine which subtype of schizophrenia is described in each scenario.

1. Jane has spent the last half hour staring in the mirror. As you approach her she turns away and giggles. When you ask what she's laughing at, she answers, but you're having difficulty understanding what she says. ____________
2. Two years ago Drew had an episode of schizophrenia, but he no longer displays the major symptoms of the disorder. He does, however, still have some bizarre thoughts and displays flat affect on occasion. ____________
3. Greg's cognitive skills and affect are relatively intact. He, however, often has delusions and hallucinations that convince him enemies are out to persecute him. ____________
4. Alice usually holds an unusual posture and is sometimes seen grimacing. ____________
5. Cameron suffers from a type of schizophrenia that is identified by disruption and incoherence in his speech and behavior. He also shows inappropriate affect, often laughing in a silly way in sad situations. ____________

### Part B

Diagnose the type of psychotic disorders described in each of the following. Choose from (a) schizophreniform disorder, (b) schizoaffective disorder, (c) delusional disorder, and (d) shared psychotic disorder.

6. Lately Dom has become more isolated because he believes his coworkers are conspiring to get him fired. He becomes agitated whenever he sees a group of employees talking and laughing, because he believes that they are plotting against him. ____________
7. Natalie reveals to her therapist that she hears numerous voices talking to her and giving her orders. Her doctor

has just sent her to this therapist for what he believes to be a major depressive episode. She had begun to sleep all the time and contemplated suicide often.

____________

8. If Shawn's schizophrenic symptoms disappeared after about 4 months and he returned to his normal life, what diagnosis might he have received? ____________
9. Elias believes the government is out to get him. He thinks agents follow him daily, monitor his calls, and read his mail. His roommate Cedric tried to convince him otherwise. However, after a year of this, Cedric began to believe Elias was correct and the government was out to get him, too. ____________

## Prevalence and Causes of Schizophrenia

Studying schizophrenia reveals the many levels on which we must decipher what makes us behave the way we do. To uncover the causes of this disorder, researchers look in several areas: (1) the possible genes involved in schizophrenia, (2) the chemical action of the drugs that help many people with this disorder, and (3) abnormalities in the working of the brains of people with schizophrenia (Tamminga, 2009). As we survey the work of many specialists, we examine many state-of-the-art techniques for studying both biological and psychosocial influences, a process that may be slow going at times but will bring new insight to your understanding of psychopathology. We now examine the nature of schizophrenia and learn how researchers have attempted to understand and treat people who have it.

### Statistics

Schizophrenia sometimes defies our desire for simplicity. We have seen how different symptoms can be displayed by individuals who would all be considered to have the disorder; in some people the symptoms develop slowly, and in others they occur suddenly. Schizophrenia is generally chronic, and most people with the disorder have a difficult time functioning in society. This is especially true of their ability to relate to others; they tend not to establish or maintain significant relationships, so many people with schizophrenia never marry or have children. Unlike the delusions of people with other psychotic disorders, the delusions of people with schizophrenia are likely to be outside the realm of possibility. Finally, even when individuals with schizophrenia improve with treatment, they are likely to experience difficulties throughout their lives.

Worldwide, the lifetime prevalence rate of schizophrenia is roughly equivalent for men and women, and it is estimated to be 0.2% to 1.5% in the general population (Mueser & Marcello, in press), which means the disorder will affect around 1% of the population at some point. Life expectancy is slightly less than average, partly because of the higher rate of suicide and accidents among people with schizophrenia. Although there is some disagreement about the distribution of schizophrenia between men and women, the difference between the sexes in age of onset is clear. For men, the likelihood of onset diminishes with age, but it can still first occur after the age of 75. The frequency of onset for women is lower than for men until age 36, when the relative risk for onset switches, with more women than men being affected later in life (Mueser & Marcello, in press). Women appear to have more favorable outcomes than do men.

### Development

The more severe symptoms of schizophrenia first occur in late adolescence or early adulthood, although we saw that there may be signs of the development of the disorder in early childhood (Murray & Bramon, 2005). Children who go on to develop schizophrenia show early clinical features such as mild physical abnormalities, poor motor coordination, and mild cognitive and social problems (Schiffman et al., 2004; Welham et al., 2008). Unfortunately, these types of early problems are not specific enough to schizophrenia—meaning they could also be signs of other problems, such as the pervasive developmental disorders we review in Chapter 14—to be able to say for sure that a particular child will later develop schizophrenia.

Up to 85% of people who later develop schizophrenia go through a *prodromal stage*—a 1- to 2-year period before the serious symptoms occur but when less severe yet unusual behaviors start to show themselves (Murray & Bramon, 2005; Yung, Phillips, Yuen, & McGorry, 2004). These behaviors (which you should recognize from Chapter 12 as symptoms seen in schizotypal personality disorders) include ideas of reference (thinking insignificant events relate directly to them), magical thinking (believing they have special abilities such as being clairvoyant or telepathic), and illusions (such as feeling the presence of another person when they are alone). In addition, other symptoms are common, such as isolation, marked impairment in functioning, and a lack of initiative, interests, or energy (Moukas, Stathopoulou, Gourzis, Beratis, & Beratis, 2010).

Once the symptoms of schizophrenia develop, it typically takes 1–2 years before the person is diagnosed and receives treatment (Woods et al., 2001). Part of this delay may be the result of hiding symptoms from others (sometimes because of increasing paranoia). Once treated, patients with this disorder will often improve. Unfortunately, most will also go through a pattern of relapse and recovery (Harvey & Bellack, 2009). This relapse rate is important when discussing the course of schizophrenia. For example, the data from one classic study show the course of schizophrenia among four prototypical groups (Zubin, Steinhauer, & Condray, 1992). About 22% of the group had one episode of schizophrenia and improved without lasting impairment. However, the remaining 78% experienced several episodes, with differing degrees of impairment between them. People with schizophrenia have a poorer prognosis than those with most of the other disorders we describe in this book—including a high risk of suicide—although a significant number of individuals can experience long periods of recovery (Jobe & Harrow, 2005). Relapses are an important subject in the field of schizophrenia; we return to this phenomenon when we discuss causes and treatment. To illustrate this complex developmental picture, ■ Figure 13.2 graphically depicts the developmental course of schizophrenia. Life stages (from before birth to the end of life) are listed across the top of

## Cultural Factors

Because schizophrenia is so complex, the diagnosis itself can be controversial. Some have argued that "schizophrenia" does not really exist but is a derogatory label for people who behave in ways outside the cultural norm (see, for example, Laing, 1967; Sarbin & Mancuso, 1980; Szasz, 1961). This concern takes us back to our discussions in the first chapter about the difficulty defining what is abnormal. Although the idea that schizophrenia exists only in the minds of mental health professionals is certainly provocative, this extreme view is contradicted by experience. We have both had a great deal of contact with people who have this disorder and with their families and friends, and the tremendous amount of emotional pain resulting from schizophrenia gives definite credence to its existence. In an interesting historical note, Kraepelin, who we described as developing the modern-day view of schizophrenia, traveled to Asia at the turn of the last century to confirm that this unusual set of behaviors was experienced by cultures other than those of Western Europe (Lauriello, Bustillo, & Keith, 2005). We now know that people in extremely diverse cultures have the symptoms of schizophrenia, which supports the notion that it is a reality for many people worldwide. Schizophrenia is thus universal, affecting all racial and cultural groups studied so far.

However, the course and outcome of schizophrenia vary from culture to culture. For example, the stressors associated with significant political, social, and economic problems that are prevalent in many areas of Africa, Latin America, and Asia may contribute to poorer outcomes for people with schizophrenia in these countries (Burns, 2009). These differences also may be the result of cultural variations or prevalent biological influences such as immunization, but we cannot yet explain these differences in outcomes.

In the United States, proportionately more African Americans receive the diagnosis of schizophrenia than Caucasians (Schwartz & Feisthamel, 2009). Research from both England and the United States suggests that people from devalued ethnic minority groups (Afro-Caribbean in England and African Americans and Puerto Ricans in the United States) may be victims of bias and stereotyping (Jones & Gray, 1986; Lewis, Croft-Jeffreys, & Anthony, 1990); in other words, they may be more likely to receive a diagnosis of schizophrenia than members of a dominant group. One prospective study of schizophrenia among different ethnic groups in London found that although the outcomes of schizophrenia appear similar across these groups, blacks were more likely to be detained against their will, brought to the hospital by police, and given emergency injections (Goater et al., 1999). The differing rates of schizophrenia, therefore, may be partially the result of *misdiagnosis* rather than to any real cultural distinctions. However, an additional factor contributing to this imbalance may be the levels of stress associated with factors such as stigma and isolation (Pinto, Ashworth, & Jones, 2008). There also may be genetic variants unique to certain racial groups that contribute to the development of schizophrenia (Glatt, Tampilic, Christie, DeYoung, & Freimer, 2004), a factor we explore in detail next.

## Genetic Influences

We could argue that no other area of abnormal psychology so clearly illustrates the enormous complexity and intriguing mystery of genetic influences on behavior as does the phenomenon of schizophrenia (Braff, Schork, & Gottesman, 2007). Despite the possibility that schizophrenia may be several different disorders, we can safely make one generalization: *Genes are responsible for making some individuals vulnerable to schizophrenia.* We look at a range of research findings from family, twin, adoptee, offspring of twins, and linkage and association studies. We conclude by discussing the compelling reasons that no one gene is responsible for schizophrenia; rather, thousands of gene variances combine to produce vulnerability (Purcell et al., 2009; Wray & Visscher, 2010).

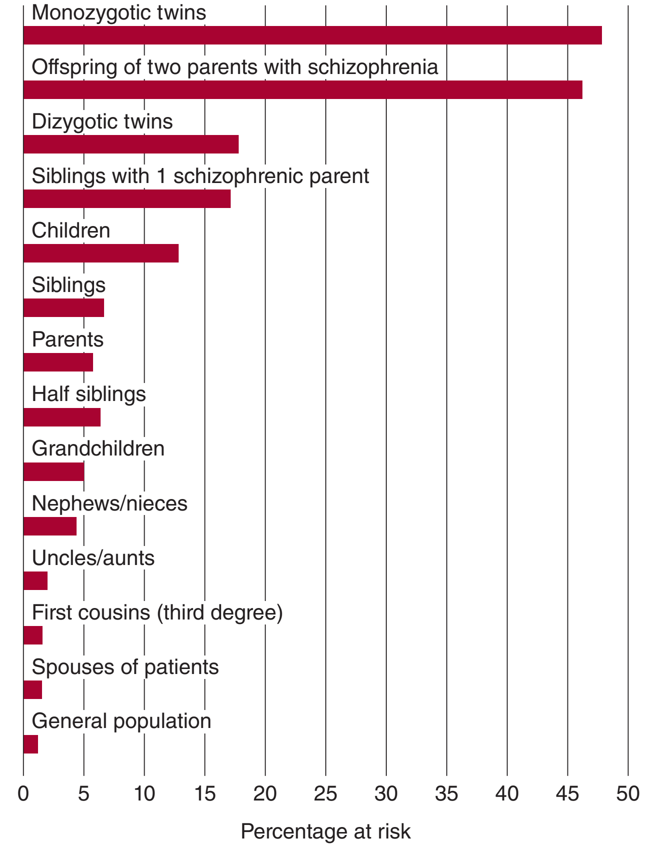
### Family Studies

In 1938, Franz Kallmann published a major study of the families of people with schizophrenia (Kallmann, 1938). Kallmann examined family members of more than 1,000 people diagnosed with schizophrenia in a Berlin psychiatric hospital. Several of his observations continue to guide research on schizophrenia. Kallmann showed that the severity of the parent's disorder influenced the likelihood of the child's having schizophrenia: The more severe the parent's schizophrenia, the more likely the children were to develop it. Another observation was important: All forms of schizophrenia (for example, catatonic and paranoid) were seen within the families. In other words, it does not appear that you inherit a predisposition for, say, paranoid schizophrenia. Instead, you may inherit a general predisposition for schizophrenia that manifests in the same form or differently from that of your parent. More recent research confirms this observation and suggests that families that have a member with schizophrenia are at risk not just for schizophrenia alone or for all psychological disorders; instead, there appears to be some familial risk for a spectrum of psychotic disorders related to schizophrenia.

In a classic analysis, Gottesman (1991) summarized the data from about 40 studies of schizophrenia, as shown in ■ Figure 13.3. The most striking feature of this graph is its orderly demonstration that the risk of having schizophrenia varies according to how many genes an individual shares with someone who has the disorder. For example, you have the greatest chance (approximately 48%) of having schizophrenia if it has affected your identical (monozygotic) twin, a person who shares 100% of your genetic information. Your risk drops to about 17% with a fraternal (dizygotic) twin, who shares about 50% of your genetic information. And having any relative with schizophrenia makes you more likely to have the disorder than someone without such a relative (about 1% if you have no relative with schizophrenia). Because family studies can't separate genetic influence from the impact of the environment, we use twin and adoption studies to help us evaluate the role of shared experiences in the cause of schizophrenia.



■ **FIGURE 13.3** Risk of developing schizophrenia. (Based on Gottesman, I. I. (1991). *Schizophrenia genesis: The origins of madness.* New York, NY: W. H. Freeman.)

### Twin Studies

If they are raised together, identical twins share 100% of their genes and 100% of their environment, whereas fraternal twins share only about 50% of their genes and 100% of their environment. If the environment is solely responsible for schizophrenia, we would expect little difference between identical and fraternal twins with regard to this disorder. If only genetic factors are relevant, both identical twins would always have schizophrenia (be concordant) and the fraternal twins would both have it about 50% of the time. Research from twin studies indicates that the truth is somewhere in the middle (Braff et al., 2007).

In one of the most fascinating of "nature's experiments," identical quadruplets, all of whom have schizophrenia, have been studied extensively. Nicknamed the "Genain" quadruplets (from the Greek, meaning "dreadful gene"), these women have been followed by David Rosenthal and his colleagues at the National Institute of Mental Health for a number of years (Rosenthal, 1963). The fictitious names of the girls reported in studies of their lives—Nora, Iris, Myra, and Hester—represent the letters NIMH for the National Institute of Mental Health. In a sense, the women represent the complex interaction between genetics and environment. All four shared the same genetic predisposition, and all were brought up in the same particularly dysfunctional household; yet the time of onset for schizophrenia, the symptoms and diagnoses, the course of the disorder, and, ultimately, their outcomes, differed significantly from sister to sister.

The case of the Genain quadruplets reveals an important consideration in studying genetic influences on behavior—*unshared environments* (Plomin, 1990). We tend to think that siblings, and especially identical multiples, are brought up exactly the same way. The impression is that "good" parents expose their children to favorable environments and "bad" parents give them unstable experiences. However, even identical siblings can have different prenatal and family experiences and therefore be exposed to varying degrees of biological and environmental stress. For example, Hester, one of the Genain sisters, was described by her disturbed parents as a habitual masturbator, and she had more social problems than her sisters as she grew up. Hester was the first to experience severe symptoms of schizophrenia, at age 18, but her sister Myra was not hospitalized until 6 years later. This unusual case demonstrates that even siblings who are close in every aspect of their lives can still have considerably different experiences physically and socially as they grow up, which may result in vastly

©Dr. Allan F. Mirsky/National Institute of Mental Health

▲ The Genain quadruplets all had schizophrenia but exhibited different symptoms over the years.

different outcomes. A follow-up on the lives of these women showed the progression of their disorder stabilized and in some cases improved when they were assessed at age 66 (Mirsky et al., 2000).

### *Adoption Studies*

Several adoption studies have distinguished the roles of the environment and genetics as they affect schizophrenia. These studies often span many years; because people often do not show the first signs of schizophrenia until middle age, researchers need to be sure all the offspring reach that point before drawing conclusions. Many schizophrenia studies are conducted in Europe, primarily because of the extensive and comprehensive records kept in countries where socialized medicine is practiced.

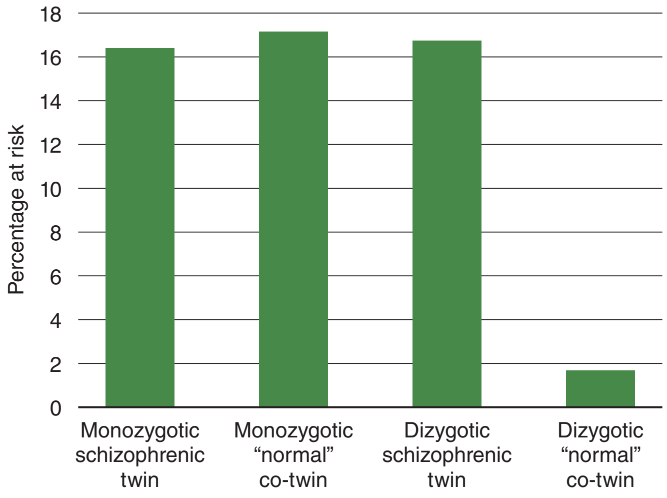
The largest adoption study is currently being conducted in Finland (Tienari, 1991). From a sample of almost 20,000 women with schizophrenia, the researchers found 190 children who had been given up for adoption. The data from this study support the idea that schizophrenia represents a spectrum of related disorders, all of which overlap genetically. If an adopted child had a biological mother with schizophrenia, that child had about a 5% chance of having the disorder (compared to about only 1% in the general population). However, if the biological mother had schizophrenia or one of the related psychotic disorders (for example, delusional disorder or schizophreniform disorder), the risk that the adopted child would have one of these disorders rose to about 22% (Tienari et al., 2003; Tienari, Wahlberg, & Wynne, 2006). Even when raised away from their biological parents, children of parents with schizophrenia have a much higher chance of having the disorder themselves. At the same time, there appears to be a protective factor if these children are brought up in healthy supportive homes. In other words, a gene–environment interaction was observed in this study, with a good home environment reducing the risk of schizophrenia (Gilmore, 2010; Wynne et al., 2006).

### *The Offspring of Twins*

Twin and adoption studies strongly suggest a genetic component for schizophrenia, but what about children who develop schizophrenia even though their parents do not? For example, the study by Tienari and colleagues (2003, 2006) we just discussed found that 1.7% of the children with nonschizophrenic parents developed schizophrenia. Does this mean you can develop schizophrenia without "schizophrenic genes"? Or are some people carriers, having the genes for schizophrenia but for some reason not showing the disorder themselves? An important clue to this question comes from research on the children of twins with schizophrenia.

In a study begun in 1971 by Margit Fischer and later continued by Irving Gottesman and Aksel Bertelsen, 21 identical twin pairs and 41 fraternal twin pairs with a history of schizophrenia were identified, along with their children (Fischer, 1971; Gottesman & Bertelsen, 1989). The researchers wanted to determine the relative likelihood that a child would have schizophrenia if her parent did and if the parent's twin had schizophrenia but the parent did not. ■ Figure 13.4 illustrates the findings from this study. For example, if your parent is an identical (monozygotic) twin with schizophrenia, you have about a 17% chance of having the disorder yourself, a figure that holds if you are the child of an unaffected identical twin whose co-twin has the disorder.

On the other hand, look at the risks for the child of a fraternal (dizygotic) twin. If your parent is the twin with schizophrenia, you have about a 17% chance of having schizophrenia yourself. However, if your parent does not have schizophrenia but your parent's fraternal twin does, your risk is only about 2%. The only way to



■ **FIGURE 13.4** Risk for schizophrenia among children of twins.

explain this finding is through genetics. The data clearly indicate that you can have genes that predispose you to schizophrenia, not show the disorder yourself, but still pass on the genes to your children. In other words, you can be a "carrier" for schizophrenia. This is some of the strongest evidence yet that people are genetically vulnerable to schizophrenia. Remember, however, there is only a 17% chance of inheritance if your parent has schizophrenia, meaning that other factors help determine who will have this disorder.

### Linkage and Association Studies

Recall from Chapter 4 that genetic linkage and association studies rely on traits such as blood types (whose exact location on the chromosome is already known) inherited in families with the disorder you are looking for—in this case, schizophrenia. Because researchers have determined the location of the genes for these traits (called *marker genes*), they can make a rough guess about the location of the disorder genes inherited with them. To date, researchers have looked at several sites for genes that may be responsible for schizophrenia. For example, regions of chromosomes 1, 2, 3, 5, 6, 8, 10, 11, 13, 20, and 22 are implicated in this disorder (Kirov & Owen, 2009).

**Endophenotypes** Genetic research on schizophrenia is evolving, and the information on the findings from these sophisticated studies is now being combined with advances in our understanding of specific deficits found in people with this disorder. Remember, in complex disorders such as this, researchers are not looking for a "schizophrenia gene" or genes. Instead, researchers try to find basic processes that contribute to the behaviors or symptoms of the disorder and then find the gene or genes that cause these difficulties—a strategy called *endophenotyping* (Braff et al., 2007).

Several potential candidates for endophenotypes for schizophrenia have been studied over the years. One of the more highly researched is called *smooth-pursuit eye movement,* or eye-tracking. Keeping their head still, typical people are able to track a moving pendulum, back and forth, with their eyes. The ability to track objects smoothly across the visual field is deficient in many people who have schizophrenia (Clementz & Sweeney, 1990; Holzman & Levy, 1977; Iacono, Bassett, & Jones, 1988); it does not appear to be the result of drug treatment or institutionalization (Lieberman et al., 1993). It also seems to be a problem for relatives of those with schizophrenia (Lenzenweger, McLachlan, & Rubin, 2007). ■ Figure 13.5 shows the decreasing likelihood of observing this abnormal eye-tracking ability the further a person is genetically from someone with schizophrenia. When all these observations are combined, they suggest an eye-tracking deficit may be an endophenotype for schizophrenia that could be used in further study.

Other such research is looking at the social, cognitive, and emotional deficits characteristic of schizophrenia. One study, for example, looked at multiple generations of families who had someone with schizophrenia (Gur et al., 2007). They tested them on a variety of skills for identified cognitive deficits in areas we described previously—such as emotion identification—and showed that specific problems were inherited in the same manner as schizophrenia (suggesting that these cognitive deficits might be endophenotypes for schizophrenia). Combining genetic research—in this case, a large family study—with neurocognitive assessment may bring us closer to understanding just what is inherited in this disorder (Braff et al., 2007).

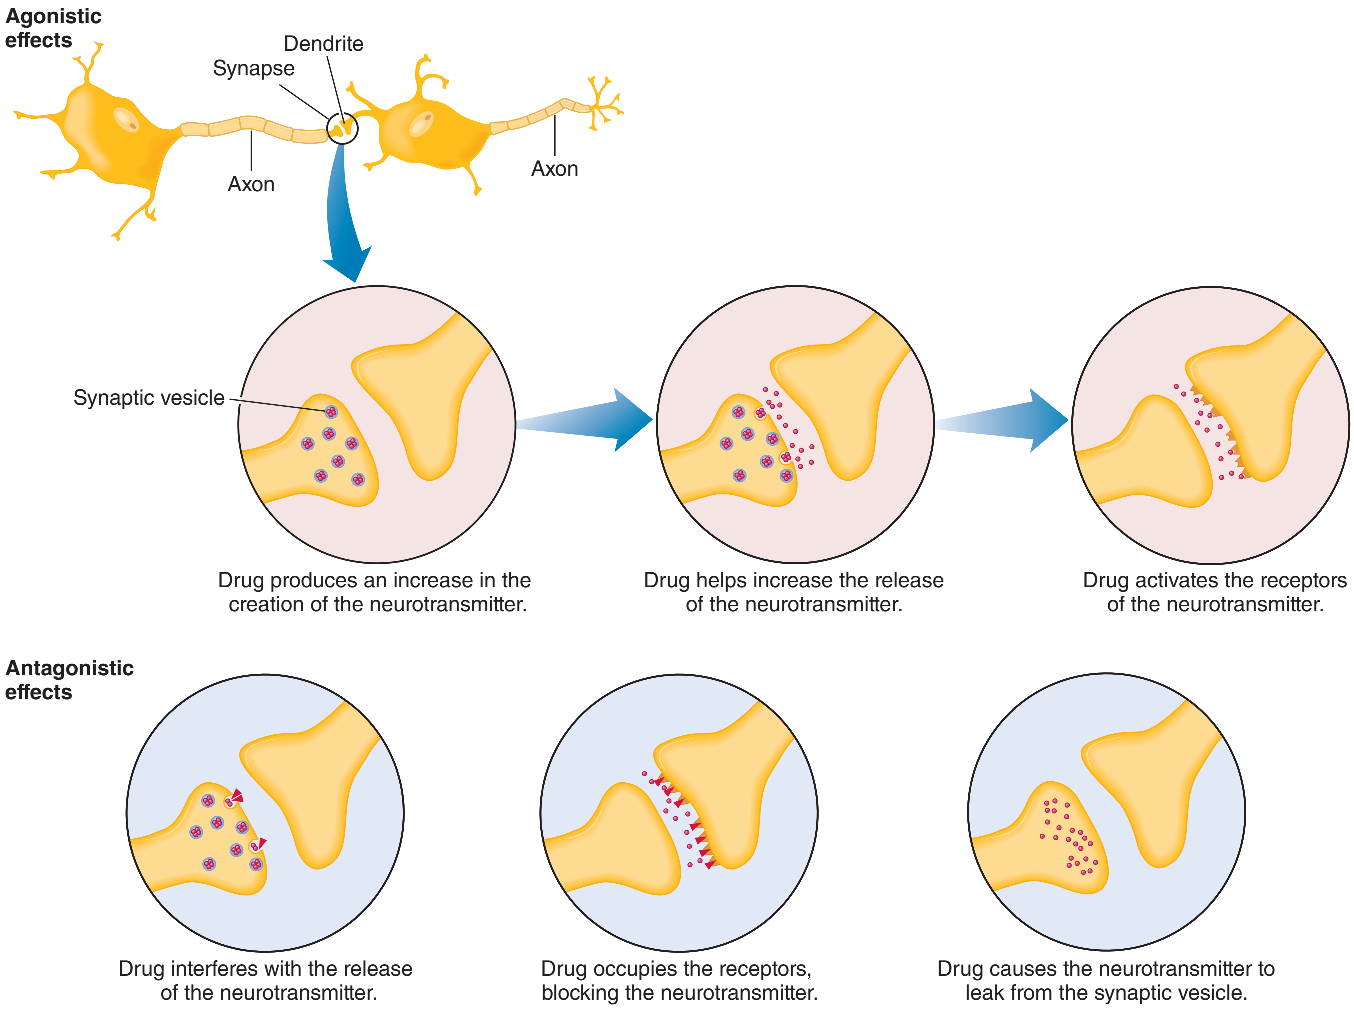
## Neurobiological Influences

The belief that schizophrenia involves a malfunctioning brain goes back as far as the writings of Kraepelin (1856–1926). It is therefore not surprising that a great deal of research has focused on the brain.

### Dopamine

One of the most enduring yet controversial theories of the cause of schizophrenia involves the neurotransmitter *dopamine* (Howes & Kapur, 2009). Before we consider the research, however, let's review briefly how neurotransmitters operate in the brain and how they are affected by neuroleptic medications, which reduce hallucinations and delusions. In Chapter 2, we discussed the sensitivity of specific neurons to specific neurotransmitters and described how they cluster throughout the brain. The top of ■ Figure 13.6 shows two neurons and the important synaptic gap that separates them. Neurotransmitters are released from the storage vessels (synaptic vesicles) at the end of the axon, cross the gap, and are taken up by receptors in the dendrite of the next axon. Chemical "messages" are transported in this way from neuron to neuron throughout the brain.

This process can be influenced in a number of ways, and the rest of Figure 13.6 illustrates some of them. The chemical messages can be increased by agonistic agents or decreased by antagonistic



Agonistic effects

Synapse
Axon
Axon
Synaptic vesicle
Drug produces an increase in the creation of the neurotransmitter.
Drug helps increase the release of the neurotransmitter.
Drug activates the receptors of the neurotransmitter.
Antagonistic effects
Drug interferes with the release of the neurotransmitter.
Drug occupies the receptors, blocking the neurotransmitter.
Drug causes the neurotransmitter to leak from the synaptic vesicle.

■ **FIGURE 13.6** Some ways drugs affect neurotransmission.

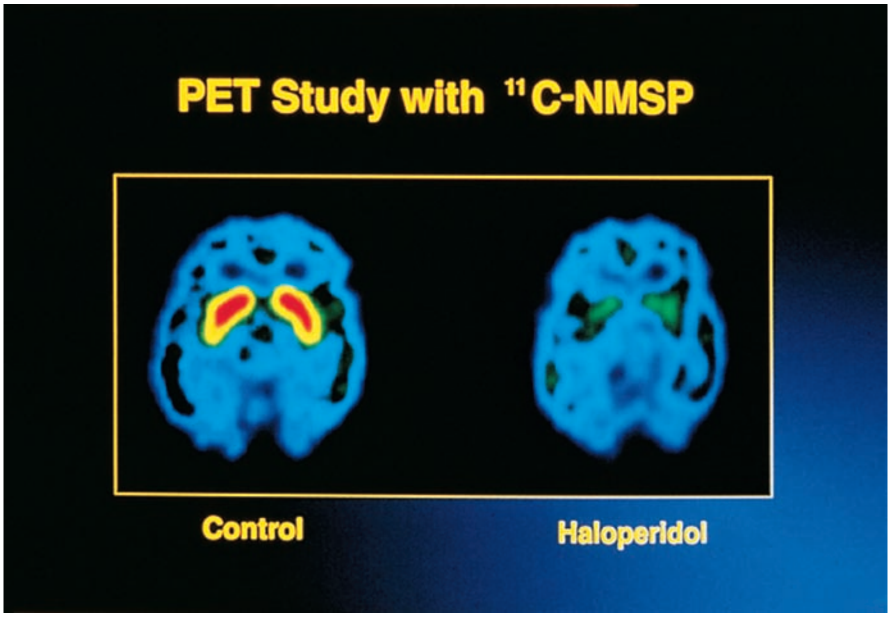
agents. (Remember the word *antagonistic* means hostile or unfriendly; in some way, this is the effect of antagonistic agents on the chemical messenger service.) Antagonistic effects slow or stop messages from being transmitted by preventing the release of the neurotransmitter, blocking uptake at the level of the dendrite, or causing leaks that reduce the amount of neurotransmitter released. On the other hand, agonistic effects assist with the transference of chemical messages and, if extreme, can produce too much neurotransmitter activity by increasing production or release of the neurotransmitter and by affecting more receptors at the dendrites.

What we've learned about antipsychotic medications points to the possibility that the dopamine system is too active in people with schizophrenia. The simplified picture in Figure 13.6 does not show that there are different receptor sites and that a chemical such as dopamine produces different results depending on which of those sites it affects. In schizophrenia, attention has focused on several dopamine sites, in particular those referred to simply as $D_1$ and $D_2$.

In a story that resembles a mystery plot, several pieces of "circumstantial evidence" are clues to the role of dopamine in schizophrenia:

1. Antipsychotic drugs (neuroleptics) often effective in treating people with schizophrenia are dopamine antagonists, partially blocking the brain's use of dopamine (Creese, Burt, & Snyder, 1976; Seeman, Lee, Chau Wong, & Wong, 1976).
2. These neuroleptic drugs can produce negative side effects similar to those in Parkinson's disease, a disorder known to be caused by insufficient dopamine.
3. The drug L-dopa, a dopamine agonist used to treat people with Parkinson's disease, produces schizophrenia-like symptoms in some people (Davidson et al., 1987).
4. Amphetamines, which also activate dopamine, can make psychotic symptoms worse in some people with schizophrenia (van Kammen, Docherty, & Bunney, 1982).

In other words, when drugs are administered that are known to increase dopamine (agonists), there is an increase in schizophrenic behavior; when drugs that are known to decrease dopamine activity (antagonists) are used, schizophrenic symptoms tend to diminish. Taking these observations together, researchers theorized that schizophrenia in some people was attributable to excessive dopamine activity.



©Dr. Dean F. Wong, Division of Nuclear Medicine and Radiation Health Sciences, Department of Radiology, The Johns Hopkins University School of Medicine

▲ These PET images show the brain of a man with schizophrenia who had never been medicated (left) and after he received haloperidol (right). The red and yellow areas indicate activity in the $D_2$ receptors; haloperidol evidently reduced dopamine activity.

Despite these observations, some evidence contradicts the dopamine theory (Javitt & Laruelle, 2006):

1. A significant number of people with schizophrenia are not helped by the use of dopamine antagonists.
2. Although the neuroleptics block the reception of dopamine quite quickly, the relevant symptoms subside only after several days or weeks, more slowly than we would expect.
3. These drugs are only partly helpful in reducing the negative symptoms (for example, flat affect or anhedonia) of schizophrenia.

In addition to these concerns, there is evidence of a "double-edged sword" with respect to schizophrenia. A medication called *olanzapine*—along with a family of similar drugs—is effective with many people who were not helped with traditional neuroleptic medications (Kane, Stroup, & Marder, 2009). That's the good news. The bad news for the dopamine theory is that olanzapine and these other new medications are weak dopamine antagonists, much less able to block the sites than other drugs (Javitt & Laruelle, 2006). Why would a medication inefficient at blocking dopamine be effective as a treatment for schizophrenia if schizophrenia is caused by excessive dopamine activity?

The answer may be that although dopamine is involved in the symptoms of schizophrenia, the relationship is more complicated than once thought (Howes & Kapur, 2009). Current thinking—based on growing evidence from highly sophisticated research techniques—points to *at least three specific neurochemical abnormalities* simultaneously at play in the brains of people with schizophrenia.

Strong evidence now leads us to believe that schizophrenia is partially the result of excessive stimulation of striatal dopamine $D_2$ receptors (Javitt & Laruelle, 2006). Recall that the striatum is part of the basal ganglia found deep within the brain. These cells control movement, balance, and walking, and they rely on dopamine to function. Current work on Huntington's disease (which involves a deterioration of motor function) is pointing to deterioration in this area of the brain. How do we know that excessive stimulation of $D_2$ receptors is involved in schizophrenia? One clue is that the most effective antipsychotic drugs all share dopamine $D_2$ receptor antagonism—meaning they help block the stimulation of the $D_2$ receptors (Ginovart & Kapur, 2010). Using brain-imaging techniques such as SPECT, scientists can view the living brain of a person with schizophrenia and can observe how the newer, "second generation" antipsychotic medications work on these specific dopamine sites.

A second area of interest to scientists investigating the cause of schizophrenia is the observation of a deficiency in the stimulation of prefrontal dopamine $D_1$ receptors (Howes & Kapur, 2009). Therefore, while some dopamine sites may be overactive (for example, striatal $D_2$), a second type of dopamine site in the part of the brain that we use for thinking and reasoning (prefrontal $D_1$ receptors) appears to be less active and may account for other symptoms common in schizophrenia. As you will see later in this chapter, people with schizophrenia display a range of deficits in the prefrontal section of the brain, and this area may be less active in people with schizophrenia (a condition known as *hypofrontality,* discussed later).

Finally, a third area of neurochemical interest involves research on alterations in prefrontal activity involving glutamate transmission (Javitt & Laruelle, 2006). Glutamate is an excitatory neurotransmitter that is found in all areas of the brain and is only now being studied in earnest. Just as we saw with dopamine (for example, $D_1$ and $D_2$ receptors), glutamate has different types of receptors, and the ones being studied for their role in schizophrenia are the *N*-methyl-d-aspartate (NMDA) receptors. And, just as researchers were led to the study of dopamine by observations from the effects of dopamine-specific drugs on behavior, the effects of certain drugs that affect NMDA receptors point to clues to schizophrenia. Two recreational drugs described in Chapter 11—phencyclidine (PCP) and ketamine—can result in psychotic-like behavior in people without schizophrenia and can exacerbate psychotic symptoms in those with schizophrenia. Both PCP and ketamine are also NMDA antagonists, suggesting that a deficit in glutamate or blocking of NMDA sites may be involved in some symptoms of schizophrenia (Goff & Coyle, 2001).

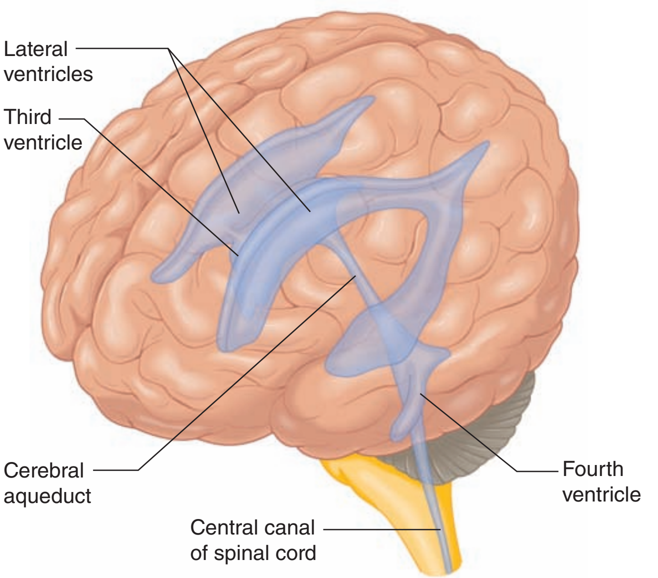
You can see that research on these two neurotransmitters and their relationship to each other is complex and awaits further clarification. However, advances in technology are leading us closer to the clues behind this enigmatic disorder and closer still to better treatments.

### Brain Structure

Evidence for neurological damage in people with schizophrenia comes from a number of observations. Many children with a parent who has the disorder, and who are therefore at risk, tend to show subtle but observable neurological problems, such as abnormal reflexes and inattentiveness (Wan, Abel, & Green, 2008). These difficulties are persistent: Adults who have schizophrenia show deficits in their ability to perform certain tasks and to attend during reaction time exercises (Cleghorn & Albert, 1990). Such findings suggest that brain damage or dysfunction may cause or accompany schizophrenia, although no one site is probably responsible for the whole range of symptoms (Belger & Dichter, 2006).

One of the most reliable observations about the brain in people with schizophrenia involves the size of the ventricles (see ■ Figure 13.7). As early as 1927, these liquid-filled cavities showed enlargement in some brains examined in people with schizophrenia (Jacobi & Winkler, 1927). Since then, more sophisticated techniques have been developed for observing the brain, and in the dozens of studies conducted on ventricle size, the great majority show abnormally large lateral ventricles in people with schizophrenia (Shenton & Kubicki, 2009). Ventricle size may not be a problem, but the dilation (enlargement) of the ventricles indicates that adjacent parts of the brain either have not developed fully or have atrophied, thus allowing the ventricles to become larger.

Ventricle enlargement is not seen in everyone who has schizophrenia. Several factors seem to be associated with this finding. For example, enlarged ventricles are observed more often in men than in women (Goldstein & Lewine, 2000). Also, ventricles seem to enlarge in proportion to age and to the duration of the schizophrenia. One study found that individuals with schizophrenia who were exposed to influenza prenatally may be more likely to have enlarged ventricles (Takei, Lewis, Jones, Harvey, & Murray, 1996). (The possible role of prenatal exposure to influenza in the development of schizophrenia is described in the next section.)



■ **FIGURE 13.7** Location of the cerebrospinal fluid in the human brain. This extracellular fluid surrounds and cushions the brain and spinal cord. It also fills the four interconnected cavities (cerebral ventricles) within the brain and the central canal of the spinal cord.

In a study of ventricle size, researchers investigated the possible role of genetics (Staal et al., 2000). Using a brain-imaging technique, magnetic resonance imaging (MRI), investigators compared brain structure among people with schizophrenia, their same-sex siblings who did not have schizophrenia, and healthy volunteers. Both the people with schizophrenia and their otherwise unaffected siblings had enlargement of the third ventricle compared to the volunteers. This suggests that the enlargement of ventricles may be related to susceptibility to schizophrenia.

We touched on the concept of unshared environments in the section on genetics (Jang, 2005; Plomin, 1990). Although twins are identical genetically, they can experience a number of environmental differences, even before they are born. For instance, in the intrauterine environment, twins must compete for nutrients, and they may not be equally successful. In addition, birth complications, such as the loss of oxygen (anoxia), could affect only one of the twins (Jang, 2005). Obstetrical complications appear often in one of a pair of twins who develops schizophrenia, and among the more severely affected if both twins have schizophrenia (McNeil, 1987). Different experiences among twins already predisposed to the disorder could damage the brain and cause the types of symptoms we associate with schizophrenia.

The frontal lobes of the brain have also interested researchers looking for structural problems associated with schizophrenia (Shenton & Kubicki, 2009). As we described in the section on neurotransmitters, this area may be less active in people with schizophrenia than in people without the disorder, a phenomenon sometimes known as *hypofrontality* (*hypo* means "less active," or "deficient"). Research by Weinberger and other scientists at the National Institute of Mental Health further refined this observation, suggesting that deficient activity in a particular area of the frontal lobes, the dorsolateral prefrontal cortex (DLPFC), may be implicated in schizophrenia (Berman & Weinberger, 1990; Weinberger, Berman, & Chase, 1988). When people with and without schizophrenia are given tasks that involve the DLPFC, less activity (measured by cerebral blood flow) is recorded in the brains of those with schizophrenia. Follow-up studies show that some individuals with schizophrenia show *hyperfrontality* (that is, too much activity), indicating that the dysfunction is reliable, but hyperfrontality displays itself differently in different people (Callicott et al., 2003; Garrity et al., 2007).

It appears that several brain sites are implicated in the cognitive dysfunction observed among people with schizophrenia, especially the prefrontal cortex, various related cortical regions, and subcortical circuits, including the thalamus and the stratum (Shenton & Kubicki, 2009). Remember that this dysfunction seems to occur *before the onset* of schizophrenia. In other words, brain damage may develop progressively, beginning before the symptoms of the disorder are apparent, perhaps prenatally.

### Prenatal and Perinatal Influences

There is evidence that the prenatal (before birth) and perinatal (around the time of birth) environment are correlated with the development of schizophrenia (van Os & Allardyce, 2009). Fetal exposure to viral infection, pregnancy complications, and delivery complications are among the environmental influences that seem to affect whether or not someone develops schizophrenia.

Several studies have shown that schizophrenia may be associated with prenatal exposure to influenza. For example, Sarnoff

Mednick and colleagues followed a large number of people after a severe Type A2 influenza epidemic in Helsinki, Finland, and found that those whose mothers were exposed to influenza during the second trimester of pregnancy were more likely to have schizophrenia than others (Cannon, Barr, & Mednick, 1991). This observation has been confirmed by some researchers (see, for example, O'Callaghan, Sham, Takei, Glover, & Murray, 1991; Venables, 1996) but not by others (Buchanan & Carpenter, 2005). The indications that viruslike diseases may cause damage to the fetal brain, which later may cause the symptoms of schizophrenia, are suggestive and may help explain why some people with schizophrenia behave the way they do (van Os & Allardyce, 2009).

The evidence of pregnancy complications (for example, bleeding) and delivery complications (for example, asphyxia or lack of oxygen) and their relationship to later schizophrenia suggest, on the surface, that this type of environmental stress may trigger the expression of the disorder (Byrne, Agerbo, Bennedsen, Eaton, & Mortensen, 2007). However, it is possible that the genes carried by the fetus that make it vulnerable to schizophrenia may themselves contribute to the birth complications (van Os & Allardyce, 2009).

The chronic and early use of marijuana (cannabis) is also being studied as a potential influence on the onset of schizophrenia (Mueser & Marcello, in press). Some evidence suggests that people who use marijuana in high doses have an increased likelihood of developing schizophrenia (Henquet et al., 2005) and that people with schizophrenia are more likely to have a cannabis use disorder than individuals without schizophrenia (Arseneault, Cannon, Witton, & Murray, 2004; Corcoran et al., 2008). However, the link between these two problems is not yet clearly understood, and there are conflicting findings about whether or not other factors may be responsible for this correlation (Foti, Kotov, Guey, & Bromet, 2010; Sevy et al., in press).

## Psychological and Social Influences

That one identical twin may develop schizophrenia and the other may not suggests that schizophrenia involves something in addition to genes. We know that early brain trauma, perhaps resulting from a second-trimester viruslike attack or obstetrical complications, may generate physical stress that contributes to schizophrenia. All these observations show clearly that schizophrenia does not fall neatly into a few simple causal packages. For instance, not all people with schizophrenia have enlarged ventricles, nor do they all have a hypofrontality or disrupted activity in their dopamine systems. The causal picture may be further complicated by psychological and social factors. We next look at research into psychosocial factors. Do emotional stressors or family interaction patterns *initiate* the symptoms of schizophrenia? If so, how might those factors cause people to relapse after a period of improvement?

### Stress

It is important to learn how much and what kind of stress makes a person with a predisposition for schizophrenia develop the disorder. Think back to the two cases we presented at the beginning of this chapter. Did you notice any precipitating events? Arthur's father had died several years earlier, and Arthur was laid off from his job around the time his symptoms first appeared. David's uncle had died the same year he began acting strangely. Were these stressful events just coincidences, or did they contribute to the men's later problems?

Researchers have studied the effects of a variety of stressors on schizophrenia. Dohrenwend and Egri (1981), for instance, observed that otherwise healthy people who engage in combat during a war often display temporary symptoms that resemble those of schizophrenia. In a classic study, Brown and Birley (1968; Birley & Brown, 1970) examined people whose onset of schizophrenia could be dated within a week. These individuals had experienced a high number of stressful life events in the 3 weeks before they started showing signs of the disorder. In a large-scale study sponsored by the World Health Organization, researchers also looked at the role of life events in the onset of schizophrenia (Day et al., 1987). This cross-national study confirmed the findings of Brown and Birley across eight research centers.

The *retrospective* nature of such research creates problems. Each study relies on after-the-fact reports, collected after the person showed signs of schizophrenia. One always wonders whether such reports are biased in some way and therefore misleading. At the same time, there are strong individual differences in how people experience the same life events, and people with schizophrenia may experience events differently than those without the disorder (Phillips, Francey, Edwards, & McMurray, 2007).

Do the symptoms of schizophrenia become worse as a result of stressful life experiences? This vulnerability–stress model of schizophrenia suggests that this is the case, and it may be helpful in predicting problems. One research study used a natural disaster—the 1994 Northridge, California, earthquake—to assess how people with schizophrenia would react to this stress when compared to those with bipolar disorder and healthy controls (Horan et al., 2007). Both patient groups reported more stress-related symptoms compared to the controls; however, the people with schizophrenia reported lower levels of self-esteem after the disaster and were more likely to engage in avoidance coping (not thinking about the problem or becoming resigned to difficulties) than the other two groups. Research on sociocultural stress, such as poverty, homelessness, and the stress of being in a new country (van Os & Allardyce, 2009), extends the types of psychosocial stressors influential in schizophrenia. Important research has begun to isolate the gene–environment interactions in this area. For example, some studies now show that particular gene variances may predict which individuals with schizophrenia will be more likely to react negatively (such as relapse) with increased stress (Myin-Germeys & Van Os, 2008). These types of studies point to how stress can impact people with schizophrenia and may suggest useful treatments (such as cognitive-behavioral therapy to help them cope more appropriately) (Phillips et al., 2007).

### Families and Relapse

A great deal of research has studied how interactions within the family affect people who have schizophrenia. For example, the term **schizophrenogenic mother** was used for a time to describe a mother whose cold, dominant, and rejecting nature was thought to cause schizophrenia in her children (Fromm-Reichmann, 1948). In addition, the term **double bind communication** was used to portray a communication style that produced conflicting messages, which, in turn, caused schizophrenia to develop (Bateson, 1959). Here, the parent presumably communicates messages that have

Courtesy of Jill Hooley

▲ Jill Hooley of Harvard University is a noted researcher of expressed emotion in families with schizophrenia.

two conflicting meanings; for example, a mother responds coolly to her child's embrace but says, "Don't you love me anymore?" when the child withdraws. Although these theories are no longer supported, they have been—and in some cases continue to be—destructive, producing guilt in parents who are persuaded that their early mistakes caused devastating consequences.

Recent work has focused more on how family interactions contribute not to the onset of schizophrenia but to relapse after initial symptoms are observed. You will see that this research is similar to the work on vulnerability to stress in general that was just discussed. Research has focused on a particular emotional communication style known as **expressed emotion (EE)**. This concept was formulated by George W. Brown and his colleagues in London. Following a sample of people who had been discharged from the hospital after an episode of schizophrenic symptoms, the researchers found that former patients who had limited contact with their relatives did better than the patients who spent longer periods with their families (Brown, 1959). Additional research results indicated that if the levels of criticism (disapproval), hostility (animosity), and emotional overinvolvement (intrusiveness) expressed by the families were high, patients tended to relapse (Brown, Monck, Carstairs, & Wing, 1962).

Other researchers have since found that ratings of high expressed emotion in a family are a good predictor of relapse among people with chronic schizophrenia (Kymalainen & Weisman de Mamani, 2008). If you have schizophrenia and live in a family with high expressed emotion, you are 3.7 times more likely to relapse than if you lived in a family with low expressed emotion (Kavanagh, 1992; Parker & Hadzi-Pavlovic, 1990). Here are examples of interviews that show how families of people with schizophrenia might communicate expressed emotion:

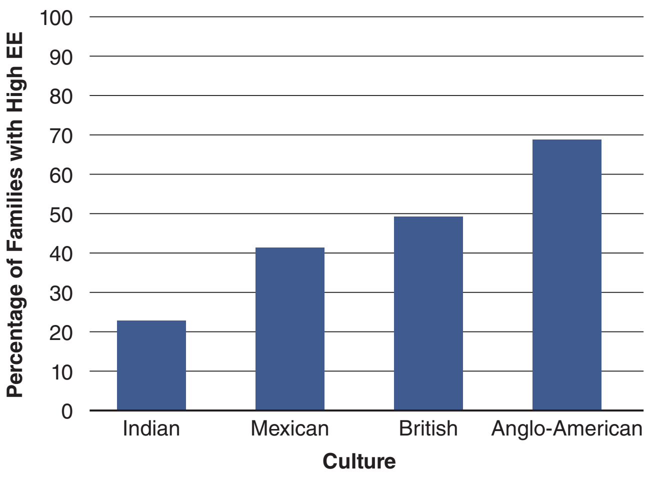
**High Expressed Emotion**

- I always say, "Why don't you pick up a book, do a crossword or something like that to keep your mind off it." That's even too much trouble.
- I've tried to jolly him out of it and pestered him into doing things. Maybe I've overdone it, I don't know.

**Low Expressed Emotion**

- I know it's better for her to be on her own, to get away from me and try to do things on her own.
- Whatever she does suits me.
- I just tend to let it go because I know that when she wants to speak she will speak. (Hooley, 1985, p. 134)

This style suggests that families with high expressed emotion view the symptoms of schizophrenia as controllable and that the hostility arises when family members think that patients just do not want to help themselves (Hooley & Campbell, 2002; McNab, Haslam, & Burnett, 2007). The literature on expressed emotion is valuable to our understanding of why symptoms of schizophrenia recur and may show us how to treat people with this disorder and their families so that they do not experience further psychotic episodes.



■ **FIGURE 13.8** Cultural differences in expressed emotion.

An interesting issue that arises when studying family influences is whether what we see is unique to our culture or universal. Looking at expressed emotion across different cultures may help us learn whether expressed emotion is a *cause* of schizophrenia (Kymalainen & Weisman de Mamani, 2008). Remember that the rate of schizophrenia is observed to be about the same worldwide, with a prevalence of about 1% in the global population. If a factor like high expressed emotion in families is a causal agent, we should see the same rates in families across cultures; however, they differ, as you can see in ■ Figure 13.8. These data come from an analysis of the concept of expressed emotion in several studies from India, Mexico, United Kingdom, and the United States (Jenkins & Karno, 1992). The differences suggest there are cultural variations in how families react to someone with schizophrenia and their reactions do not cause the disorder (Weisman de Mamani, Kymalainen, Rosales, & Armesto, 2007). However, critical and hostile environments clearly provide additional stressors that can, in turn, lead to more relapses.

## Concept Check 13.2

Check your understanding of genetic vulnerability by filling in the blanks of the statements associated with family, twin, and adoption studies. Choose from (a) higher, (b) lower, (c) equal, (d) severity, (e) type, (f) identical twin, (g) specific, (h) fraternal twin, and (i) general.

1. The greatest risk of having schizophrenia is in those who have a(n) ____________ or ____________ with schizophrenia. Any relative with schizophrenia will make your chances of developing the disorder ____________ than those of the general population.

2. Raised in a home other than that of their biological parents, adopted children of parents with schizophrenia have a(n) ____________ chance of having the disorder themselves. Children of people with schizophrenia adopted into families without schizophrenia have a ____________-than-average chance of having schizophrenia.
3. The likelihood of a child's having schizophrenia is influenced by the ____________ of the parent's disorder. One may inherit a predisposition for ____________ schizophrenia that is the same or different from that of the parent.

## Treatment of Schizophrenia

If you remember our descriptions of Arthur and David, you will recall their families' concern for them. Arthur's mother spoke of the "living nightmare," and David's aunt expressed concern for both her safety and David's. In each case, the family was desperate to help, but what do you do for someone who has delusions, hears his dead uncle's voice, or can't communicate complete thoughts? The search for help has taken many paths, sometimes down some disturbing roads; for example, in the 1500s primitive surgery was conducted to remove the "stone of madness," which was thought to cause disturbed behavior. As barbaric as this practice may seem today, it is not different from the prefrontal lobotomies performed on people with schizophrenia as late as the 1950s. This procedure severed the frontal lobes from the lower portion of the brain, which sometimes calmed the patient but also caused cognitive and emotional deficits. Even today, some societies use crude surgical procedures to eliminate the symptoms of schizophrenia. In Kenya, for instance, Kisii tribal doctors listen to their patients to find the location of the noises in their heads (hallucinations), then get them drunk, cut out a piece of scalp, and scrape the skull in the area of the voices (Mustafa, 1990).

▲ An early 16th-century painting of psychosurgery, in which part of the brain is removed to treat mental illness.

In the Western world today, treatment usually begins with one of the neuroleptic drugs invaluable in reducing the symptoms of schizophrenia for many people. They are typically used with a variety of psychosocial treatments to reduce relapse, compensate for skills deficits, and improve cooperation for taking the medications (Kane et al., 2009).

### Biological Interventions

Researchers have assumed for more than 100 years that schizophrenia requires some form of biological intervention. Kraepelin, who so eloquently described dementia praecox in the late 19th century, saw the disorder as a brain disease. Lacking a biological treatment, he routinely recommended that the physician use "good patience, kindly disposition, and self-control" to calm excited patients (Nagel, 1991). This approach was seen as only a temporary way of helping the person through disturbing times and was not thought to be an actual treatment.

During the 1930s, several novel biological treatments were tried. One approach was to inject massive doses of insulin—the drug that given in smaller doses is used to treat diabetes—to induce comas in people suffering from schizophrenia. Insulin coma therapy was thought for a time to be helpful, but closer examination showed it carried great risk of serious illness and death. During this time, *psychosurgery,* including prefrontal lobotomies, was introduced, and in the late 1930s, electroconvulsive therapy (ECT) was advanced as a treatment for schizophrenia. As with earlier drastic treatments, initial enthusiasm for ECT faded because it was found not to be beneficial for most people with schizophrenia—although it is still used with a limited number of people today, sometimes in combination with antipsychotic medications (Braga & Petrides, 2005). As we explained in Chapter 7, ECT is sometimes recommended for people who experience severe episodes of depression.

#### *Antipsychotic Medications*

A breakthrough in the treatment of schizophrenia came during the 1950s with the introduction of several drugs that relieved symptoms in many people (Kane et al., 2009). Called *neuroleptics* (meaning "taking hold of the nerves"), these medications provided the first real hope that help was available for people with schizophrenia. When they are effective, neuroleptics help people think more clearly and reduce hallucinations and delusions. They work by affecting the positive symptoms (delusions, hallucinations, and agitation) and to a lesser extent the negative and disorganized ones, such as social deficits. Table 13.2 shows the classes of these drugs (based on their chemical structure) and their trade names.

Recall from our discussion of the dopamine theory of schizophrenia that the neuroleptics are dopamine antagonists. One of their major actions in the brain is to interfere with the dopamine neurotransmitter system. However, they can also affect other systems,

**TABLE 13.2** Commonly Used Antipsychotic Medications

| Class | Example* | Degree of Extrapyramidal Side Effects |
|---|---|---|
| Conventional Antipsychotics | | |
| Phenothiazines | Chlorpromazine/*Thorazine* | Moderate |
| | Fluphenazine/*Prolixin* | High |
| | Mesoridazine/*Serentil* | Low |
| | Perphenazine/*Trilafon* | High |
| | Thioridazine/*Mellaril* | Low |
| | Trifluoperazine/*Stelazine* | High |
| Butyrophenone | Haloperidol/*Haldol* | High |
| Others | Loxapine/*Loxitane* | High |
| | Molindone/*Moban* | Low |
| | Thiothixene/*Navane* | High |
| Second-Generation Agents | | |
| | Aripiprazole/*Abilify* | Low |
| | Clozapine/*Clozaril* | Low |
| | Olanzapine/*Zyprexa* | Low |
| | Quetiapine/*Seroquel* | Low |
| | Risperidone/*Risperdal* | Low |
| | Ziprasidone/*Geodon* | Low |

such as the serotonergic and glutamate system. We are just beginning to understand the mechanisms by which these drugs work.

In general, each drug is effective with some people and not with others. Clinicians and patients often must go through a trial-and-error process to find the medication that works best, and some individuals do not benefit significantly from any of them. The earliest neuroleptic drugs, called conventional or first-generation antipsychotics (such as Haldol and Thorazine), are effective for approximately 60% of people who try them (Kane et al., 2009). However, many people are not helped by antipsychotics or experience unpleasant side effects. Fortunately, some people respond well to newer medications—sometimes called atypical or second-generation antipsychotics; the most common are risperidone and olanzapine. These newer drugs hold promise for helping patients who were previously unresponsive to medications (Leucht et al., 2009); also, it was initially thought that these drugs had fewer serious side effects than the conventional antipsychotics. However, two large-scale studies—one conducted in the United States (called the "Clinical Antipsychotic Trials of Intervention Effectiveness" or CATIE) (Stroup & Lieberman, 2010) and one in the United Kingdom (called the "Cost Utility of the Latest Antipsychotic Drugs in Schizophrenia Study" or CUtLASS) (Jones et al., 2006)—found that the second-generation drugs were no more effective or better tolerated than the older drugs (Lewis & Lieberman, 2008). These results point out how important it is to carefully study the outcomes of all new treatments.

### Noncompliance with Medication: Why?

Despite the optimism generated by the effectiveness of antipsychotics, they work only when they are taken properly, and many people with schizophrenia do not routinely take their medication. David frequently "cheeked" the Haldol pills that were helpful in reducing his hallucinations, holding them in his mouth until he was alone then spitting them out. In the large-scale study we just mentioned, 74% of those studied had stopped taking their medications 18 months after initial use (Lieberman et al., 2005).

A number of factors seem to be related to patients' noncompliance with a medication regimen, including negative doctor–patient relationships, cost of the medication, and poor social support (Miller, McEvoy, Jest, & Marder, 2006). Not surprisingly, negative side effects are a major factor in patient refusal. Antipsychotics can produce a number of unwanted physical symptoms, such as grogginess, blurred vision, and dryness of the mouth. Because the drugs affect neurotransmitter systems, more serious side effects, called *extrapyramidal symptoms,* can also result (Kane et al., 2009). These symptoms include the motor difficulties similar to those experienced by people with Parkinson's disease, sometimes called parkinsonian symptoms. *Akinesia* is one of the most common; it includes an expressionless face, slow motor activity, and monotonous speech. Another extrapyramidal symptom is *tardive dyskinesia,* which involves involuntary movements of the tongue, face, mouth, or jaw and can include protrusions of the tongue, puffing of the cheeks, puckering of the mouth, and chewing movements. Tardive dyskinesia seems to result from long-term use of high doses of antipsychotic medication and is often irreversible. During the first 5 years of use, 3% to 5% of people taking this medication display tardive dyskinesia, with the risk increasing over time (Kane, 2006). These serious negative side effects have justifiably concerned people who otherwise benefit from the drugs.

©Radius Images/Jupiter Images

▲ One of the major obstacles to drug treatment for schizophrenia is compliance. Patients discontinue their medication for a variety of reasons, including the negative side effects.

To learn what patients themselves say, Windgassen (1992) questioned 61 people who had had recent onsets of schizophrenia. About half reported the feeling of sedation or grogginess as an unpleasant side effect: “I always have to fight to keep my eyes open,” “I felt as though I was on drugs . . . drowsy, and yet really wound up” (p. 407). Other complaints included deterioration in the ability to think or concentrate (18%), problems with salivation (16%), and blurred vision (16%). Although a third of the patients felt the medications were beneficial, about 25% had a negative attitude toward them. A significant number of people who could benefit from antipsychotic medications find them unacceptable as a treatment, which may explain the relatively high rates of refusal and noncompliance (Pratt, Mueser, Driscoll, Wolfe, & Bartels, 2006; Yamada et al., 2006).

Researchers have made this a major treatment issue in schizophrenia, realizing that medications can’t be successful if they aren’t taken regularly. Researchers hoped compliance rates would improve with the introduction of injectable medications. Instead of taking an oral antipsychotic every day, patients can have their medications injected every few weeks. Unfortunately, noncompliance remains an issue, primarily because patients do not return to the hospital or clinic for repeated doses (Kane et al., 2009). Psy-

## Innovative Approaches

### Using Virtual Reality in Assessment and Treatment

Is there a role for new technologies in the diagnosis and treatment of schizophrenia? Creative researchers are answering this question in a number of exciting developments for the field. One study looked to improve the understanding of schizophrenia by using virtual reality technology to simulate multiple cognitive tasks (Sorkin, Weinshall, Modai, & Peled, 2006). Researchers created a gamelike task to test aspects of working memory and perseveration (focusing on the same things repeatedly) and found not only that this approach could create real-life simulations that revealed deficits but also that the tasks could be fun. A study carried out at King’s College in London tested the nature of paranoia in a virtual reality environment among groups with low paranoia, nonclinical paranoia, and those with persecutory delusions (Freeman, Pugh, Vorontsova, Antley, & Slater, 2010). Researchers constructed a virtual scene that depicts a London subway and created avatars as passengers that at times would look at the study participant (see accompanying photos).

Across the groups there were meaningful differences in levels of anxiety, worry, interpersonal sensitivity, and depression according to their previous levels of paranoia. This type of assessment provided a safe environment in which to assess and study persecutory paranoia in the groups. Other research is using this technology to assist older persons with schizophrenia improve their cognitive and general motor skills (for example, by having them push away colorful balls that are floating toward them in a virtual world) (Chan, Ngai, Leung, & Wong, 2010). Again, these virtual assessments and treatments provide clinicians with controllable and safer environments in which to study and treat persons with schizophrenia.

The bottom photo shows what the participants see. This technology allows researchers to closely control positions and facial expressions of the virtual people on the train.

chosocial interventions are now used not only to treat schizophrenia but also to increase medication-taking compliance by helping patients communicate better with professionals about their concerns.

An interesting but as yet not-well-validated treatment for the hallucinations experienced by many people with schizophrenia involves exposing the individual to magnetic fields. Called *transcranial magnetic stimulation,* this technique uses wire coils to repeatedly generate magnetic fields—up to 50 times per second—that pass through the skull to the brain. This input seems to interrupt temporarily the normal communication to that part of the brain. Hoffman and colleagues (2000, 2003) used this technique to stimulate the area of the brain involved in hallucinations for individuals with schizophrenia who experienced auditory hallucinations. They found that many of the individuals experienced improvement following transcranial magnetic stimulation. Again, more research is required to assess the true value of this technique for people with hallucinations (Vercammen et al., 2009).

## Psychosocial Interventions

Historically, a number of psychosocial treatments have been tried for schizophrenia, reflecting the belief that the disorder results from problems in adapting to the world because of early experiences (Tenhula, Bellack, & Drake, 2009). Many therapists have thought that individuals who could achieve insight into the presumed role of their personal histories could be safely led to deal with their current situations. Although clinicians who take a traditional psychodynamic or psychoanalytic approach to therapy continue to use this type of treatment, research suggests that their efforts at best may not be beneficial and at worst may be harmful (Mueser & Berenbaum, 1990; Scott & Dixon, 1995).

Today, few believe that psychological factors cause people to have schizophrenia or that traditional psychotherapeutic approaches will cure them. Nevertheless, you will see that psychological methods have an important role. Despite the great promise of drug treatment, the problems with ineffectiveness, inconsistent use, and relapse suggest that by themselves drugs may not be effective with many people. As with a number of the disorders discussed in this text, recent work in the area of psychosocial intervention has suggested the value of an approach that uses both kinds of treatment (Mueser & Marcello, in press).

Until relatively recently, most people with severe and chronic cases of schizophrenia were treated in hospital settings. During the 19th century, inpatient care involved "moral treatment," which emphasized improving patients' socialization, helping them establish routines for self-control, and showing them the value of work and religion (Tenhula et al., 2009). Various types of such "milieu" treatments (changing the physical and social environment—usually to make institutional settings more homelike) have been popular, but, with one important exception, none seems to have helped people with schizophrenia.

Gordon Paul and Robert Lentz conducted pioneering work in the 1970s at a mental health center in Illinois (Paul & Lentz, 1977). Borrowing from the behavioral approaches used by Ted Ayllon and Nate Azrin (1968), Paul and Lentz designed an environment for inpatients that encouraged appropriate socialization, participation in group sessions, and self-care such as bed making while discouraging violent outbursts. They set up an elaborate **token economy**, in which residents could earn access to meals and small luxuries by behaving appropriately. A patient could, for example, buy cigarettes with the tokens he earned for keeping his room neat. On the other hand, a patient would be fined (lose tokens) for being disruptive or otherwise acting inappropriately. This incentive system was combined with a full schedule of daily activities. Paul and Lentz compared the effectiveness of applied behavioral (or social learning) principles to traditional inpatient environments. In general, they found that patients who went through their program did better than others on social, self-care, and vocational skills, and more of them could be discharged from the hospital. This study was one of the first to show that people suffering from the debilitating effects of schizophrenia can learn to perform some skills they need to live more independently.

During the years since 1955, many efforts have combined to halt the routine institutionalization of people with schizophrenia in the United States (Fakhoury & Priebe, 2007). This trend has occurred partly because of court rulings that limit involuntary hospitalization (as we saw in Arthur's case) and partly because of the relative success of antipsychotic medication. The bad news is that policies of deinstitutionalization have often been ill conceived, with the result that many people who have schizophrenia or other serious psychological disorders are homeless—the number is estimated at between 150,000 and 200,000 people in the United States alone (Pearson, Montgomery, & Locke, 2009). The good news is that more attention is being focused on supporting these people in their communities, among their friends and families. The trend is away from creating better hospital environments and toward the perhaps more difficult task of addressing complex problems in the less predictable and insecure world outside. So far, only a small fraction of the growing number of homeless individuals with mental disorders is being helped.

One of the more insidious effects of schizophrenia is its negative impact on a person's ability to relate to other people. Although not as dramatic as hallucinations and delusions, problems with social skills can be the most visible impairment displayed by

▲ A mother is glad to have her daughter home from a psychiatric hospital, but acknowledges that "Now the real struggle begins."

people with schizophrenia and can prevent them from getting and keeping jobs and making friends. Clinicians attempt to reteach social skills such as basic conversation, assertiveness, and relationship building to people with schizophrenia (Mueser & Marcello, in press).

Therapists divide complex social skills into their component parts, which they model. Then the clients do role-playing and ultimately practice their new skills in the "real world," all the while receiving feedback and encouragement at signs of progress. This isn't as easy as it may sound. For example, how would you teach someone to make a friend? Many skills are involved, such as maintaining eye contact when you talk to someone and providing the prospective friend with some (but not too much) positive feedback on her own behavior ("I really enjoy talking to you"). Such individual skills are practiced and then combined until they can be used naturally (Swartz, Lauriello, & Drake, 2006). The challenge of teaching social skills, as with all therapies, is to maintain the effects over a long period.

In addition to social skills, programs often teach a range of ways people can adapt to their disorder yet live in the community. At the Independent Living Skills Program at the University of California, Los Angeles, for example, the focus is on helping people take charge of their own care by such methods as identifying signs that warn of a relapse and learning how to manage their medication (see Table 13.3) (Liberman, 2007). Preliminary evidence indicates that this type of training may help prevent relapses by people with schizophrenia, although longer-term outcome research is needed to see how long the effects last. To address some obstacles to this much-desired maintenance, such programs combine skills training with the support of a multidisciplinary team that provides services directly in the community, which seems to reduce hospitalization (Swartz et al., 2006). The more time and effort given to these services, the more likely the improvement.

In our discussion of the psychosocial influences on schizophrenia, we reviewed some work linking the person's social and emotional environments to the recurrence of schizophrenic episodes (McNab et al., 2007). It is logical to ask whether families could be helped by learning to reduce their level of expressed emotion and whether this would result in fewer relapses and better overall functioning for people with schizophrenia. Several studies have addressed these issues in a variety of ways (Falloon et al., 1985; Hogarty et al., 1986, 1991), and behavioral family therapy has been used to teach the families of people with schizophrenia to be more supportive (Dixon & Lehman, 1995; Mueser, Liberman, & Glynn, 1990). Research on professionals who provide care for people who have schizophrenia, and who may display high levels of expressed emotion, is also an active area of study (Grice et al., 2009).

In contrast to traditional therapy, behavioral family therapy resembles classroom education (Lefley, 2009). Family members are informed about schizophrenia and its treatment, relieved of the myth that they caused the disorder, and taught practical facts about antipsychotic medications and their side effects. They are also helped with communication skills so that they can become more empathic listeners, and they learn constructive ways of ex-

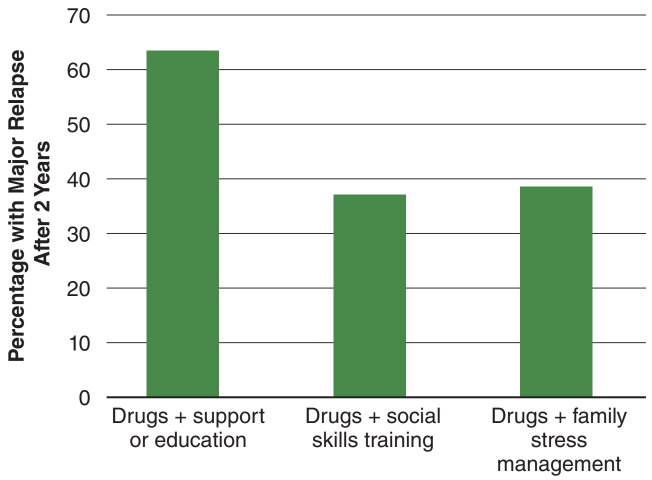
*Source:* Reprinted, with permission, from Eckman, T. A., Wirshing, W. C., Marder, S. R., Liberman, R. P., Johnston-Cronk, K., Zimmermann, K., & Mintz, J. (1992). Techniques for training schizophrenic patients in illness self-management: A controlled trial. *American Journal of Psychiatry, 149,* 1549–1555, © 1992 American Psychiatric Association.

pressing negative feelings to replace the harsh criticism that characterizes some family interactions. In addition, they learn problem-solving skills to help them resolve conflicts that arise. Like the research on social skills training, outcome research suggests that the effects of behavioral family therapy are significant during the first year but less robust 2 years after intervention (Montero, Masanet, Bellver, & Lacruz, 2006; Montero et al., 2005). This type of therapy, therefore, must be ongoing if patients and their families are to benefit from it.

Adults with schizophrenia face great obstacles to maintaining gainful employment. Their social skills deficits make reliable job performance and adequate employee relationships a struggle. To address these difficulties, some programs focus on vocational rehabilitation, such as supportive employment. Supportive employment involves providing coaches who give on-the-job training, and these efforts can help some people with schizophrenia maintain meaningful jobs (Mueser & Marcello, in press).

Research suggests that individual social skills training, family intervention, and vocational rehabilitation may be helpful additions to biological (drug) treatment for schizophrenia. Significant relapses may be avoided or delayed by such psychosocial interventions. ■ Figure 13.9 illustrates the studies reviewed by one group (Falloon, Brooker, & Graham-Hole, 1992), which show that multilevel treatments reduce the number of relapses among people receiving drug therapy in comparison with simple social support or educational efforts.



■ **FIGURE 13.9** Studies on treatment of schizophrenia from 1980 to 1992. (From Falloon, I. R. H., Brooker, C., & Graham-Hole, V. (1992). Psychosocial interventions for schizophrenia. *Behaviour Change, 9,* 238–245.)

Where treatment occurs, it has expanded over the years from locked wards in large mental hospitals, to family homes, to local communities. In addition, the services have expanded to include self-advocacy and self-help groups. Former patients have organized programs such as Fountain House in New York City to provide mutual support. Psychosocial clubs have differing models, but all are "person centered" and focus on obtaining positive experiences through employment opportunities, friendship, and empowerment. Many see this consumer-run self-help model as an added component to more specific interventions such as social skills training, family intervention, and medical management of symptoms. Some research indicates that participation may help reduce relapses, but as it is also possible that those who participate may be a special group of individuals, it is difficult to interpret improvements (Goering et al., 2006).

Because schizophrenia is a complex disorder that affects multiple areas of functioning, effective treatment is carried out at several levels. Table 13.4 lists six approaches to treatment that have proved effective in assisting these individuals to achieve higher quality lives. Probably the most extensively studied program is the assertive community treatment (ACT) program that grew out of work by researchers in Madison, Wisconsin (Swartz et al., 2006). ACT involves using a multidisciplinary team of professionals to provide broad-ranging treatment across all domains, including medication management, psychosocial treatment, and vocational training and support. As you can see, one approach alone is not sufficient to address the many needs of people with schizophrenia and their families (Mueser & Marcello, in press).

**TABLE 13.4** An Integrative Treatment Approach

| Treatment | Description |
|---|---|
| Collaborative psychopharmacology | Using antipsychotic medications to treat the main symptoms of the disorder (hallucinations, delusions), as well as using other medications for secondary symptoms (for example, antidepressant medication for people with secondary depression) |
| Assertive community treatment | Providing support in the community, with emphasis on small caseloads for care providers, services in the community setting rather than a clinic, and 24-hour coverage |
| Family psychoeducation | Assisting family members, including educating them about the disorder and its management, helping them reduce stress and tension in the home, and providing social support |
| Supportive employment | Providing sufficient support before and during employment so that the person can find and keep a meaningful job |
| Illness management and recovery | Helping the individual become an active participant in treatment, including providing education about the disorder, teaching effective use of medication strategies for collaborating with clinicians, and coping with symptoms when they reoccur |
| Integrated dual-disorders treatment | Treating coexisting substance use |

## Treatment across Cultures

Treatment of schizophrenia and its delivery differ from one country to another and across cultures within countries. For example, the vast majority of the Xhosa people of South Africa who have schizophrenia report using traditional healers who sometimes recommend the use of oral treatments to induce vomiting, enemas, and the slaughter of cattle to appease the spirits (Koen, Niehaus, Muller, & Laurent, 2008). Hispanics may be less likely than other groups to seek help in institutional settings, relying instead on family support (Liberman & Kopelowicz, 2009). Adapting treatments to make them culturally relevant—in this case, adding important relatives to the social skills training of Latinos with schizophrenia—is essential for effectiveness (Kopelowicz, Mintz, Liberman, Zarate, & Gonzalez-Smith, 2004). In one interesting study, beliefs about symptoms and treatments were compared between British and Chinese populations (Furnham & Wong, 2007). Native Chinese hold more religious beliefs about both the causes and the treatments of schizophrenia than those living in England—for example, endorsing statements such as, "Schizophrenia is due to evil done in a previous life" and "Ancestor worship (burning candles and joss sticks) will help treat schizophrenia." These different beliefs translate into practice—with the British using more biological, psychological, and community treatments and the Chinese relying more on alternative medicine (Furnham & Wong, 2007). Supernatural beliefs about the cause of schizophrenia among family members in Bali lead to limited use of antipsychotic medication in treatment (Kurihara, Kato, Reverger, & Gusti Rai Tirta, 2006). In many countries in Africa, people with schizophrenia are kept in prisons, primarily because of the lack of adequate alternatives (Mustafa, 1990). In general, the movement from housing people in large institutional settings to community care is ongoing in most Western countries.

## Prevention

One strategy for preventing a disorder such as schizophrenia—which typically first shows itself in early adulthood—is to identify and treat children who may be at risk for getting the disorder later in life. In our discussion of genetics, we noted that approximately 17% of the children born to parents who have schizophrenia are likely themselves to develop the disorder. These high-risk children have been the focus of several studies.

A classic at-risk study was initiated in the 1960s by Sarnoff Mednick and Fini Schulsinger (1965, 1968). They identified 207 Danish children of mothers who had severe cases of schizophrenia and 104 control children born to mothers who had no history of the disorder. The average age of these children was about 15 when they were first identified, and the researchers followed them for 10 more years to determine whether any factors had predicted who would and would not develop schizophrenia. We have already discussed pregnancy and delivery-related complications. Mednick and Schulsinger also identified *instability of early family rearing environment,* which suggests that environmental influences may trigger the onset of schizophrenia (Cannon et al., 1991). Poor parenting may place additional strain on a vulnerable person who is already at risk.

As we await the outcomes of long-term studies, other approaches may prove valuable for reducing the rates of this disorder. For example, we have seen that factors such as birth complications and certain early illnesses (for example, viruses) may trigger the onset of schizophrenia, especially among those individuals who are genetically predisposed. Therefore, interventions such as vaccinations against viruses for women of childbearing age and interventions related to improving prenatal nutrition and care may be effective preventive measures (McGrath, 2010).

▲ In China, acupuncture and herbal medicine are often used with antipsychotic medications for schizophrenia.

### Concept Check 13.3

Read the descriptions and then match them to the following words: (a) olanzapine, (b) extrapyramidal symptoms, (c) serotonin, (d) dopamine, (e) metabolites, (f) token economy, (g) vocational rehabilitation, (h) social skills training, (i) family intervention.

1. Setting up an elaborate ____________ in which patients are fined for disruptive or inappropriate behavior and rewarded for appropriate behavior is beneficial in hospitals.
2. In ____________ clinicians attempt to reteach such behaviors as basic conversation, assertiveness, and relationship building to people with schizophrenia.
3. Aside from social skills training, two psychosocial treatments for schizophrenia, ____________ (teaching family members to be supportive) and ____________ (teaching meaningful jobs), may be helpful.
4. Recent studies sometimes indicate that the relationship of the neurotransmitters ____________ and ____________ may explain some positive symptoms of schizophrenia.
5. Because antipsychotic medications may cause serious side effects, some patients stop taking them. One serious side effect is called ____________, which may include parkinsonian symptoms.
6. Difficult cases of schizophrenia seem to improve with a serotonin and dopamine antagonist called ____________.

**On the Spectrum**

### Emerging Views of Schizophrenia

Although the *DSM-IV-TR* does not use this language, there is a recognition in the field of schizophrenia that the group of diagnoses that we cover in this chapter (and in others) constitute *schizophrenia spectrum disorders*. In fact, Eugen Bleuler, who coined the term *schizophrenia* in his book *Dementia Praecox or the Group of Schizophrenias* (1911), identified the different variants that were all included within this spectrum (Heckers, 2009). The *DSM* has struggled with this concept in its varied presentations over the years, and, as we describe in this chapter, *DSM-IV-TR* currently lists five subtypes of schizophrenia (paranoid, disorganized, catatonic, undifferentiated, and residual) as well as other related psychotic disorders that fall under this heading (schizophreniform, schizoaffective, delusional, brief psychotic, and shared psychotic disorders). In addition, a personality disorder (schizotypal personality disorder, discussed in Chapter 12) and possibly two mood disorders (psychotic bipolar disorder and psychotic depression) are also considered by some to be included under this umbrella category of schizophrenia spectrum disorders. All of these difficulties seem to share features of extreme reality distortion (for example, hallucinations, delusions).

Discussions for *DSM-5* include the possible removal of the subtypes of schizophrenia and instead adding a dimensional rating for some of the core symptoms of schizophrenia (American Psychiatric Association, 2010). For example, one possibility being discussed is to rate the extent to which an individual has and is distressed by the following dimensions: hallucinations, delusions, disorganization, abnormal psychomotor behavior, restricted emotional expression, avolition, impaired cognition, depression, and mania. This would allow clinicians the ability to provide a richer description of the complex problems faced by an individual that often go unspecified within single labels (for example, paranoid schizophrenia) that people are assigned. What is required is a thorough study of the soundness of these types of dimensional structures and a determination of whether or not they represent valid diagnoses.

## Summary

### Clinical Description, Symptoms, and Subtypes

- Schizophrenia is characterized by a broad spectrum of cognitive and emotional dysfunctions that include delusions and hallucinations, disorganized speech and behavior, and inappropriate emotions.
- The symptoms of schizophrenia can be divided into positive, negative, and disorganized. Positive symptoms are active manifestations of abnormal behavior, or an excess or distortion of normal behavior, and include delusions and hallucinations. Negative symptoms involve deficits in normal behavior on such dimensions as affect, speech, and motivation. Disorganized symptoms include rambling speech, erratic behavior, and inappropriate affect.
- *DSM-IV-TR* divides schizophrenia into five subtypes. People with the paranoid type of schizophrenia have prominent delusions or hallucinations while their cognitive skills and affect remain relatively intact. People with the disorganized type of schizophrenia tend to show marked disruption in their speech and behavior; they also show flat or inappropriate affect. People with the catatonic type of schizophrenia have unusual motor responses, such as remaining in fixed positions (waxy flexibility), excessive activity, and being oppositional by remaining rigid. In addition, they display odd mannerisms with their bodies and faces, including grimacing. People who do not fit neatly into these subtypes are classified as having an undifferentiated type of schizophrenia. Some people who have had at least one episode of schizophrenia but who no longer have major symptoms are diagnosed as having the residual type of schizophrenia.
- Several other disorders are characterized by psychotic behaviors, such as hallucinations and delusions; these include schizophreniform disorder (which includes people who experience the symptoms of schizophrenia for less than 6 months); schizoaffective disorder (which includes people who have symptoms of schizophrenia and who exhibit the characteristics of mood disorders, such as depression and bipolar affective disorder); delusional disorder (which includes people with a persistent belief that is contrary to reality, in the absence of the other characteristics of schizophrenia); brief psychotic disorder (which includes people with one or more positive symptoms, such as delusions, hallucinations, or disorganized speech or behavior over the course of less than a month); and shared psychotic disorder (which includes individuals who develop delusions simply as a result of a close relationship with a delusional individual).

### Prevalence and Causes of Schizophrenia

- A number of causative factors have been implicated for schizophrenia, including genetic influences, neurotransmitter imbalances, structural damage to the brain caused by a prenatal viral infection or birth injury, and psychological stressors.
- Relapse appears to be triggered by hostile and critical family environments characterized by high expressed emotion.

### Treatment of Schizophrenia

- Successful treatment for people with schizophrenia rarely includes complete recovery. However, the quality of life for these individuals can be meaningfully affected by combining antipsychotic medications with psychosocial approaches, employment support, and community-based and family interventions.
- Treatment typically involves antipsychotic drugs that are usually administered with a variety of psychosocial treatments, with the goal of reducing relapse and improving skills in deficits and compliance in taking the medications. The effectiveness of treatment is limited, because schizophrenia is typically a chronic disorder.

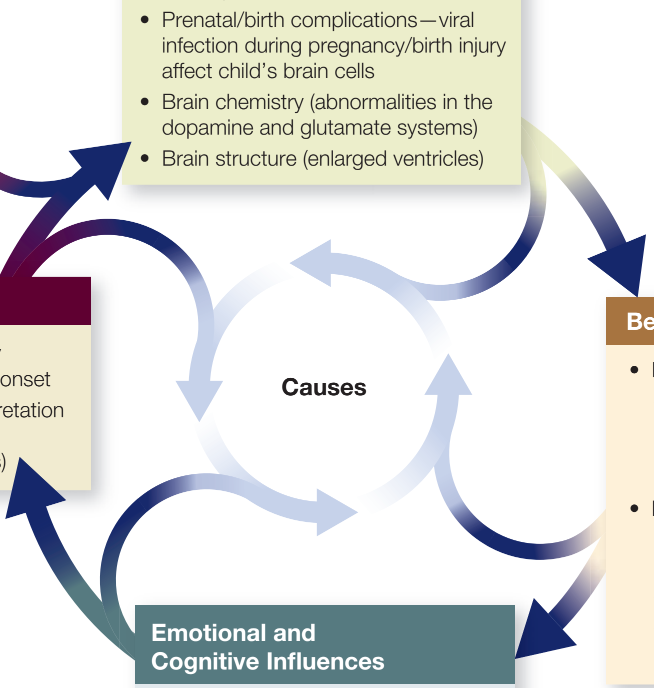
# Exploring Schizophrenia

› Schizophrenia disrupts perception of the world, thought, speech, movement, and almost every other aspect of daily functioning.

› Usually chronic with a high relapse rate; complete recovery from schizophrenia is rare.



- Stressful, traumatic life event
- High expressed emotion (family criticism, hostility, and/or intrusion)
- Sometimes no obvious trigger

**Trigger**

**Biological Influences**

- Inherited tendency (multiple genes) to develop disease
- Prenatal/birth complications—viral infection during pregnancy/birth injury affect child's brain cells
- Brain chemistry (abnormalities in the dopamine and glutamate systems)
- Brain structure (enlarged ventricles)

©Dynamic Graphics/Jupiter Images

**Behavioral Influences**

- **Positive symptoms:**
  —Active manifestations of abnormal behavior (delusions, hallucinations, disorganized speech, odd body movements, or catatonia)
- **Negative symptoms:**
  —Flat affect (lack of emotional expression)
  —Avolition (lack of initiative, apathy)
  —Alogia (relative absence in amount or content of speech)

**Emotional and Cognitive Influences**

- Interaction styles that are high in criticism, hostility, and emotional overinvolvement can trigger a relapse

**Social Influences**

- Environment (early family experiences) can trigger onset
- Culture influences interpretation of disease/symptoms (hallucinations, delusions)

## SYMPTOMS OF SCHIZOPHRENIA

People with schizophrenia do not all show the same kinds of symptoms. Symptoms vary from person to person and may be cyclical. Common symptoms include:

| Symptoms | | |
|---|---|---|
| **Delusions** | ©Photodisc/Getty Images | • Unrealistic and bizarre beliefs not shared by others in the culture<br>• May be delusions of grandeur (that you are really Mother Teresa or Napoleon) or delusions of persecution (the cyclist who believed her competitors were sabotaging her by putting pebbles in the road) |
| **Hallucinations** | ©Photodisc/Getty Images | • Sensory events that aren't based on any external event (hearing voices, seeing people who have died)<br>• Many have auditory hallucinations (David hears his dead uncle talking to him) |
| **Disorganized Speech** |  ©Royalty Free/Corbis | • Jumping from topic to topic<br>• Talking illogically (not answering direct questions, going off on tangents)<br>• Speaking in unintelligible words and sentences |
| **Behavioral Problems** | ©Dynamic Graphics/Jupiter Images | • Pacing excitably, wild agitation<br>• Catatonic immobility<br>• Waxy flexibility (keeping body parts in the same position when they are moved by someone else)<br>• Inappropriate dress (coats in the summer, shorts in the winter)<br>• Inappropriate affect<br>• Ignoring personal hygiene |
| **Withdrawal** |  ©Photodisc/Getty Images | • Lack of emotional response (flat speech, little change in facial expressions)<br>• Apathy (little interest in day-to-day activities)<br>• Delayed and brief responses in conversation<br>• Loss of enjoyment in pleasurable activities (eating, socializing, sex) |

## TYPES OF SCHIZOPHRENIA

| Paranoid | Disorganized | Catatonic | Residual | Undifferentiated |
|---|---|---|---|---|
| • Delusions of grandeur or persecution<br>• Hallucinations (especially auditory)<br>• Higher level of functioning between episodes<br>• May have stronger familial link than other types | • Disorganized speech and/or behavior<br>• Immature emotionality (inappropriate affect)<br>• Chronic and lacking in remissions | • Alternating immobility and excited agitation<br>• Unusual motor responses (waxy flexibility, rigidity)<br>• Odd facial or body mannerisms (often mimicking others)<br>• Rare | • Has had at least one schizophrenic episode but no longer shows major symptoms<br>• Still shows "leftover" symptoms (social withdrawal, bizarre thoughts, inactivity, flat affect) | • Symptoms of several types that taken together do not neatly fall into one specific category |

## STUDENT LEARNING OUTCOMES*

| | |
|---|---|
| Demonstrate knowledge and understanding representing appropriate breadth and depth in selected content areas of psychology: | › Biological bases of behavior and mental processes, including physiology, sensation, perception, comparative, motivation, and emotion (APA SLO 1.2.a (3)) ***(see textbook pages 524–526)*** |
| Use the concepts, language, and major theories of the discipline to account for psychological phenomena. | › Describe behavior and mental processes empirically, including operational definitions (APA SLO 1.3.a) ***(see textbook pages 503–506, 510–511, 514–516, 520–524)*** |
| Identify appropriate applications of psychology in solving problems, such as: | › Origin and treatment of abnormal behavior (APA SLO 4.2.b) ***(see textbook pages 507–510, 511–514, 516–520, 524–529)*** |

---

* Portions of this chapter cover learning outcomes suggested by the American Psychological Association (2007) in their guidelines for the undergraduate psychology major. Chapter coverage of these outcomes is identified above by APA Goal and APA Suggested Learning Outcome (SLO).

## Common Developmental Disorders

Almost all disorders described in this book are developmental disorders in the sense that they change over time. Most disorders originate in childhood, although the full presentation of the problem may not manifest itself until much later. Disorders that show themselves early in life often persist as the person grows older, so the term *childhood disorder* may be misleading. In this chapter, we cover those disorders that are revealed in a clinically significant way during a child's developing years and are of concern to families and educators. Remember, however, that these difficulties often persist through adulthood and are typically lifelong problems, not problems unique to children.

Again, a number of difficulties and, indeed, distinct disorders begin in childhood. In certain disorders, some children are fine except for difficulties with talking. Others have problems relating to their peers. Still other children have a combination of conditions that significantly hinder their development, as illustrated by the case of Timmy.

### **TIMMY** | *The Boy Who Looked Right Through You*

Timmy, a beautiful blond baby, was born with the umbilical cord wrapped around his neck, so he had been without oxygen for an unknown period. Nonetheless, he appeared to be a healthy little boy. His mother later related that he was a good baby who rarely cried, although she was concerned he didn't like to be picked up and cuddled. His family became worried about his development when he was 2 years old and didn't talk (his older sister had at that age). They also noticed that he didn't play with other children; he spent most of his time alone, spinning plates on the floor, waving his hands in front of his face, and lining up blocks in a certain order.

The family's pediatrician assured them that Timmy was just developing at a different rate and would grow out of it. When, at age 3, Timmy's behavior persisted, his parents consulted a second pediatrician. Neurological examinations revealed nothing unusual but suggested, on the basis of Timmy's delay in learning such basic skills as talking and feeding himself, that he had mild intellectual disability.

Timmy's mother did not accept this diagnosis, and over the next few years she consulted numerous other professionals and received numerous diagnoses (including childhood schizophrenia, childhood psychosis, and developmental delay). By age 7, Timmy still didn't speak or play with other children, and he was developing aggressive and self-injurious behaviors. His parents brought him to a clinic for children with severe disabilities. Here, Timmy was diagnosed as having autism.

The clinic specialists recommended a comprehensive educational program of intensive behavioral intervention to help Timmy with language and socialization and to counter his increasing tendency to engage in tantrums. The work continued daily for approximately 10 years, both at the clinic and at home. During this time, Timmy learned to say only three words: "soda," "cookie," and "Mama." Socially, he appeared to like other people (especially adults), but his interest seemed to center on their ability to get him something he wanted, such as a favorite food or drink. If his surroundings were changed in even a minor way, Timmy became disruptive and violent to the point of hurting himself; to minimize his self-injurious behavior, the family took care to ensure that his surroundings stayed the same as much as possible. However, no real progress was made toward eliminating his violent behavior, and as he grew bigger and stronger, he became increasingly difficult to work with; he hurt his mother physically on several occasions. With great reluctance, she institutionalized Timmy when he was 17.

As clinicians have grown to appreciate the far-reaching effects of childhood problems and the importance of early intervention in treating most disorders, they have become more interested in understanding the diversity of severe problems experienced in early life. Timmy was diagnosed with autism in the early 1970s. Almost four decades later, we know more—although still not enough—about how to help children who have autism. Who can say what the prognosis for Timmy might be today, especially if he were diagnosed correctly at age 2 instead of at age 7?

## What Is Normal? What Is Abnormal?

Before we discuss specific disorders, we need to address the broad topic of development in relation to disorders usually first diagnosed in infancy, childhood, or adolescence. What can we learn from children like Timmy, and what effect do the early disruptions in their skills have on their later lives? Does it matter when in the developmental period certain problems arise? Are disruptions in development permanent, thus making any hope for treatment doubtful?

Recall that in Chapter 2 we described developmental psychopathology as the study of how disorders arise and how they change with time. Childhood is considered particularly important because the brain changes significantly for several years after birth; this is also when critical developments occur in social, emotional, cognitive, and other important competency areas. These changes mostly follow a pattern: The child develops one skill before acquiring the next. Although this pattern of change is only one aspect of development, it is an important concept at this point because it implies that any disruption in the development of early skills will, by the very nature of this sequential process, disrupt the development of later skills. For example, some researchers believe that people with autism suffer from a disruption in early social development, which prevents them from developing important social relationships, even with their parents. From a developmental perspective, the absence of early and meaningful social relationships has serious consequences. Children whose motivation to interact with others is disrupted may have a more difficult time learning to communicate; that is, they may not want to learn to speak if other people are not important to them. Researchers don't know whether a disruption in communication skills is a direct outcome of the disorder or a by-product of disrupted early social development.

Understanding this type of developmental relationship is important for several reasons. Knowing what processes are disrupted will help us understand the disorder better and may lead to more appropriate intervention strategies. It may be important to identify children with attention deficit/hyperactivity disorder, for example, because their problems with impulsivity may interfere with their ability to create and maintain friendships, an important developmental consideration. Similarly, identifying a disorder such as autism at an early age is important for these children so that their social deficits can be addressed before they affect other skill domains, such as language and communication. Too often, people see early and pervasive disruptions in developmental skills (such as you saw with Timmy) and expect a negative prognosis, with the problems predetermined and permanent. However, remember that biological and psychosocial influences continuously interact with each other. Therefore, even for disorders such as attention deficit/hyperactivity disorder and autism that have clear biological bases, the presentation of the disorder is different for each individual. Changes at the biological or the psychosocial level may reduce the impact of the disorder.

One note of caution is appropriate here. There is real concern in the profession, especially among developmental psychologists, that some workers in the field may view aspects of normal development as symptoms of abnormality. For example, *echolalia,* which involves repeating the speech of others, was once thought to be a sign of autism. However, when we study the development of speech in children without disorders, we find that repeating what someone else says is an intermediate step in language development. In children with autism, therefore, echolalia is just a sign of relatively delayed language skills and not a symptom of their disorder (Tager-Flusberg et al., 2009). Knowledge of development is important for understanding the nature of psychological disorders.

With that caveat in mind, we now examine several disorders usually diagnosed first in infancy, childhood, or adolescence, including *attention deficit/hyperactivity disorder,* which involves characteristics of inattention or hyperactivity and impulsivity, and *learning disorders,* which are characterized by one or more difficulties in areas such as reading and writing. We then focus on *autistic disorder,* a more severe disability, in which the child shows significant impairment in social interactions and communication and has restricted patterns of behavior, interest, and activities, and we discuss the less severe Asperger's disorder. Finally, we examine *intellectual disability,* which involves considerable deficits in cognitive abilities.

## Attention Deficit/Hyperactivity Disorder

Do you know people who flit from activity to activity, who start many tasks but seldom finish one, who have trouble concentrating, and who don't seem to pay attention when others speak? These people may have **attention deficit/hyperactivity disorder (ADHD)**, one of the most common reasons children are referred for mental health services in the United States (Durand, in press-a; Greenhill & Hechtman, 2009). The primary characteristics of such people include a pattern of inattention, such as not paying attention to school- or work-related tasks, or of hyperactivity and impulsivity. These deficits can significantly disrupt academic efforts, as well as social relationships. Consider the case of Danny.

### **DANNY** | *The Boy Who Couldn't Sit Still*

Danny, a handsome 9-year-old boy, was referred to us because of his difficulties at school and at home. Danny had a great deal of energy and loved playing most sports, especially baseball. Academically, his work was adequate, although his teacher reported that his performance was diminishing and she believed he would do better if he paid more attention in class. Danny rarely spent more than a few minutes on a task without some interruption: He would get up out of his seat, rifle through his desk, or constantly ask questions. His peers were frustrated with him because he was equally impulsive during their interactions: He never finished a game, and in sports he tried to play all positions simultaneously.

At home, Danny was considered a handful. His room was in a constant mess because he became engaged in a game or activity only to drop it and initiate something else. Danny's parents reported that they often scolded him for not carrying out some task, although the reason seemed to be that he forgot what he was doing rather than that he deliberately tried to defy them. They also said that, out of their own frustration, they sometimes grabbed him by the shoulders and yelled, "Slow down!" because his hyperactivity drove them crazy.

### *Clinical Description*

Danny has many characteristics of ADHD. Like Danny, people with this disorder have a great deal of difficulty sustaining their attention on a task or activity (Barkley, 2006e). As a result, their tasks are often unfinished and they often seem not to be listening when someone else is speaking. In addition to this serious disruption in attention, some people with ADHD display motor hyperactivity. Children with this disorder are often described as fidgety in school, unable to sit still for more than a few minutes. Danny's restlessness in his classroom was a considerable source of concern for his teacher and peers, who were frustrated by his impatience and excessive activity. In addition to hyperactivity and problems sustaining attention, impulsivity—acting apparently without thinking—is a common complaint made about people with ADHD. For instance, during meetings of his baseball team, Danny often shouted responses to the coach's questions even before the coach had a chance to finish his sentence.

For ADHD, the fourth edition, text revision, of the *Diagnostic and Statistical Manual (DSM-IV-TR)* differentiates three types of symptoms. The first includes problems of *inattention.* People may appear not to listen to others; they may lose necessary school assignments, books, or tools; and they may not pay enough attention to details, making careless mistakes. The second type of symptom includes *hyperactivity,* which includes fidgeting, having trouble sitting for any length of time, always being on the go. The third general symptom is *impulsivity,* which includes blurting out answers before questions have been completed and having trouble waiting turns. Either the first (inattention) or the second and third (hyperactivity and impulsivity) symptoms must be present for someone to be diagnosed with ADHD.

Inattention, hyperactivity, and impulsivity often cause other problems that appear secondary to ADHD. Academic performance tends to suffer, especially as the child progresses in school. The cause of this poor performance is not known. It could be a result of the problems with attention and impulsivity characteristic of ADHD, and in some children this can be made worse by factors such as concurrent learning disabilities, which are common in boys with ADHD (Barkley, 2006b). Children with ADHD are likely to be unpopular and rejected by their peers (Nijmeijer et al., 2008). Here, the difficulty appears to be directly related to the behaviors symptomatic of ADHD. For example, one study found that young girls with ADHD in general were likely to be rejected by peers but that this likelihood was more pronounced in those with hyperactivity, impulsivity, and inattention when compared to girls who had only the inattentive type (Hinshaw, 2002).

### *Statistics*

ADHD is estimated to occur in 3% to 7% of school-age children in the United States, and an important analysis of prevalence suggests that the disorder is found in about 5.2% of the child populations across all regions of the world (Polanczyk, de Lima, Horta, Biederman, & Rohde, 2007). This finding of comparable rates of ADHD worldwide is important because debates continue to rage about the validity of ADHD as a real disorder. Some people believe that children who are just normally "active" are being misdiagnosed with ADHD. Previously, geographic differences were noted in the number of people diagnosed with this disorder. Children were more likely to receive the label of ADHD in the United States than anywhere else. Based on these different rates of diagnosis, some have argued that ADHD in children is simply a cultural construct—meaning that the behavior of these children is typical from a developmental perspective and it is Western society's intolerance (due to the loss of extended family support, pressure to succeed academically, and busy family life) that causes labeling ADHD as a disorder (Timimi & Taylor, 2004). However, with improvements in diagnosis worldwide, countries that previously reported lower rates of ADHD are now finding similar numbers of these children being brought to the attention of helping professionals (Barkley, 2006e). This change suggests that the disorder may not simply be a reflection of a lack of tolerance on the part of teachers or parents in the United States for active or impulsive children but rather is an indication that ADHD is a valid disorder that affects a significant number of children all over the world (Moffitt & Melchior, 2007).

Boys are 3 times more likely to be diagnosed with ADHD than girls, and this discrepancy increases for children being seen in clinics (Spencer, Biederman, & Mick, 2007). The reason for this gender difference is largely unknown. It may be that adults are more tolerant of hyperactivity among girls, who tend to be less active than boys with ADHD. Boys tend to be more aggressive, which will more likely result in attention by mental health professionals (Barkley, 2006e). Girls with ADHD, on the other hand, tend to display more behaviors referred to as "internalizing"—specifically, anxiety and depression (Mick et al., in press).

The higher prevalence of boys identified as having ADHD has led some to question whether the *DSM-IV-TR* diagnostic criteria for this disorder are applicable to girls. Here is the quandary: Most research over the last several decades has used young boys as participants. This focus on boys may have been the result of their active and disruptive behaviors, which caused concern among families and school personnel and therefore prompted research into the nature, causes, and treatment of these problems. More boys displayed these behaviors, which made it easier to find participants to study. But did this almost singular focus on boys result in ignoring how young girls experience this disorder?

This concern is being raised by some psychologists, including Kathleen Nadeau (a clinical psychologist who specializes in girls with ADHD), who argues that more research is needed on ADHD

**DSM-IV-TR** **Table 14.1** Diagnostic Criteria for Attention Deficit/Hyperactivity Disorder

**A.** Either (1) or (2):

  **1.** Six (or more) of the following symptoms of inattention have persisted for at least 6 months to a degree that is maladaptive and inconsistent with developmental level:

    Inattention

    **a.** Often fails to give close attention to details or makes careless mistakes in schoolwork, work, or other activities
    **b.** Often has difficulty sustaining attention in tasks or play activities
    **c.** Often does not seem to listen when spoken to directly
    **d.** Often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace (not due to oppositional behavior or failure to understand instructions)
    **e.** Often has difficulty organizing tasks and activities
    **f.** Often avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort (such as schoolwork or homework)
    **g.** Often loses things necessary for tasks or activities (e.g., toys, school assignments, pencils, books, or tools)
    **h.** Is often easily distracted by extraneous stimuli
    **i.** Is often forgetful in daily activities

  **2.** Six (or more) of the following symptoms of hyperactivity/impulsivity have persisted for at least 6 months to a degree that is maladaptive and inconsistent with developmental level:

    Hyperactivity

    **a.** Often fidgets with hands or feet or squirms in seat
    **b.** Often leaves seat in classroom or in other situations in which remaining seated is expected
    **c.** Often runs about or climbs excessively in situations in which it is inappropriate (in adolescents or adults, may be limited to subjective feelings of restlessness)
    **d.** Often has difficulty playing or engaging in leisure activities quietly
    **e.** Is often "on the go" or often acts as if "driven by a motor"
    **f.** Often talks excessively

    Impulsivity

    **g.** Often blurts out answers before questions have been completed
    **h.** Often has difficulty awaiting turn
    **i.** Often interrupts or intrudes on others (e.g., butts into conversations or games)

**B.** Some hyperactive/impulsive or inattentive symptoms that caused impairment were present before age 7 years.

**C.** Some impairment from the symptoms is present in two or more settings (e.g., at school [or work] and at home).

**D.** There must be clear evidence of clinically significant impairment in social, academic, or occupational functioning.

**E.** The symptoms do not occur exclusively during the course of a pervasive developmental disorder, schizophrenia, or other psychotic disorder and are not better accounted for by another mental disorder (e.g., mood disorder, anxiety disorder, dissociative disorder, or a personality disorder).

in girls: "Girls experience significant struggles that are often overlooked because their ADHD symptoms bear little resemblance to those of boys" (Crawford, 2003, p. 28). She says that girls with ADHD were neglected because their symptoms differ so dramatically from boys' symptoms, although to date there is little firm evidence for these differences (Babinski et al., in press). Just as researchers are now exploring ADHD among adults, in addition to children, more research is now addressing the relative lack of research on girls and women. This expansion of research across age and gender bodes well for a fuller understanding of the disorder.

Children with ADHD are first identified as different from their peers around age 3 or 4; their parents describe them as active, mischievous, slow to toilet train, and oppositional (Conners, March, Frances, Wells, & Ross, 2001). The symptoms of inattention, impulsivity, and hyperactivity become increasingly obvious during the school years. Despite the perception that children grow out of ADHD, their problems usually continue: it is estimated that about half of the children with ADHD have ongoing difficulties through adulthood (McGough, 2005). Over time, children with ADHD seem to be less impulsive, although inattention persists. During adolescence, the impulsivity manifests itself in different areas; for example, teens with ADHD are at greater risk for pregnancy and contracting sexually transmitted infections. They are also more likely to have driving difficulties, such as crashes; to be cited for speeding; and to have their licenses suspended (Barkley, 2006a). In short, although the manifestations of ADHD change as people grow older, many of their problems persist.

Up to 80% of children with ADHD are diagnosed with one or more other disorders as well (Brown, 2009). This information is important for several reasons. First, it speaks to the causes of the disorder, which may overlap with others. Second, it tells clinicians to look for other problems in these children that may complicate efforts to treat them. Common comorbid disorders in children with ADHD include anxiety, depression, and disruptive behavior (Barkley, 2006c). Similarly, almost 90% of adults with ADHD are likely to have at least one other disorder, including disruptive behavior, depression, anxiety, and substance use disorders (Brown, 2009).

As you can see, diagnosing children with ADHD is complicated. Several other *DSM-IV-TR* disorders, also found in children, appear to overlap significantly with this disorder. Specifically, oppositional defiant disorder (ODD), conduct disorder, and bipolar disorder all have characteristics seen in children with ADHD. ODD is a *DSM-IV-TR* disorder that includes symptoms such as "often loses temper," "argues with adults," "often deliberately annoys people," "touchy and easily annoyed by others," and "often spiteful and vindictive." The impulsivity and hyperactivity observed in children with ADHD can manifest themselves in some of these symptoms. It's been estimated that at least half of those with ADHD could also be diagnosed with ODD (Durand, in press-a). Similarly, conduct disorder—which, as you saw in Chapter 12, can be a precursor to antisocial personality disorder—is also observed in many children with ADHD (Nock, Kazdin, Hiripi, & Kessler, 2006). Bipolar disorder—which, you will recall from Chapter 7, is one of the mood disorders—also overlaps significantly with ADHD. This overlap can complicate diagnosis in these children.

### Causes

As with many other disorders, we are at a period when important information about the genetics of ADHD is beginning to be uncovered (Kebir, Tabbane, Sengupta, & Joober, 2009; Waldman & Gizer, 2006). Researchers have known for some time that ADHD is more common in families in which one person has the disorder. For example, the relatives of children with ADHD have been found to be more likely to have ADHD themselves than would be expected in the general population (Fliers et al., 2009). It is important to note that these families display an increase in psychopathology in general, including conduct disorder, mood disorders, anxiety disorders, and substance abuse (Faraone et al., 2000). This research and the comorbidity in the children themselves suggest that some shared genetic deficits may contribute to the problems experienced by individuals with these disorders (Brown, 2009).

ADHD is considered to be highly influenced by genetics, with a relatively small role played by environmental influences in the cause of the disorder when compared to many other disorders we discuss in this book. As with other disorders, researchers are finding that multiple genes are responsible for ADHD (Nikolas & Burt, 2010). Research in this area is following the same progression as for other disorders and involves large collaborative studies across many laboratories worldwide. Most attention to date focuses on genes associated with the neurochemical dopamine, although norepinephrine, serotonin, and gamma-aminobutyric acid (GABA) are also implicated in the cause of ADHD. More specifically, there is strong evidence that ADHD is associated with the dopamine $D_4$ receptor gene, the dopamine transporter gene (DAT1), and the dopamine $D_5$ receptor gene. DAT1 is of particular interest because methylphenidate (Ritalin)—one of the most common medical treatments for ADHD—inhibits this gene and increases the amount of dopamine available. Such research helps us understand at a microlevel what might be going wrong and how to design new interventions.

As with several other disorders we've discussed, researchers are looking for endophenotypes, those basic deficits—such as specific attentional problems—characteristic of ADHD. The goal is to link these deficits to specific brain dysfunctions. Not surprisingly, specific areas of current interest for ADHD are the brain's attention system, working memory functions, inattentiveness, and impulsivity. Researchers are now trying to tie specific genetic defects to these cognitive processes to make the link between genes and behavior. Some research indicates that poor "inhibitory control" (the ability to stop responding to a task when signaled) may be common among both children with ADHD and their unaffected family members (siblings and parents) and may be one genetic marker (an endophenotype) for this disorder (Goos, Crosbie, Payne, & Schachar, 2009).

The strong genetic influence in ADHD does not rule out any role for the environment (Ficks & Waldman, 2009). In one of a growing number of gene–environment interaction studies of ADHD, for example, researchers found that children with a specific mutation involving the dopamine system (called the DAT1 genotype) were more likely to exhibit the symptoms of ADHD if their mothers smoked during pregnancy (Kahn, Khoury, Nichols, & Lanphear, 2003). Prenatal smoking seemed to interact with this genetic predisposition to increase the risk for hyperactive and impulsive behavior. Other research is now pointing to additional environmental factors, such as low socioeconomic status and parental marital instability and discord, as involved in these gene–environment interactions (Ficks & Waldman, 2009).

For several decades, ADHD has been thought to involve brain damage, and this notion is reflected in the previous use of labels such as "minimal brain damage" or "minimal brain dysfunction" (Ross & Pelham, 1981). The rapid advances in scanning technology now permit us to see just how the brain may be involved in this disorder. A great deal of research on the structure and the function of the brain for children with this disorder has been conducted over the past few years. In general, researchers now know that the overall volume of the brain in those with this disorder is slightly smaller (3% to 4%) than in children without this disorder (Narr et al., 2009). A number of areas in the brains of those with ADHD appear affected (Valera, Faraone, Murray, & Seidman, 2007). In addition, more research is starting to focus on the structure and function of the brain in adults with ADHD.

A variety of such toxins as allergens and food additives have been considered as possible causes of ADHD over the years, although little evidence supports the association. The theory that food additives such as artificial colors, flavorings, and preservatives are responsible for the symptoms of ADHD has been highly controversial. Feingold (1975) presented this view, along with recommendations for eliminating these substances as a treatment for ADHD. Hundreds of thousands of families have put their children on the Feingold diet, despite arguments by some that the diet has little or no effect on the symptoms of ADHD (Barkley, 1990; Kavale & Forness, 1983). However, some large-scale research now suggests that there may be a small but measurable impact of artificial food colors and additives on the behavior of young children. One study found that 3-year-old and 8- to 9-year-old children who consumed typical amounts of preservatives (sodium benzoate) and food colorings had increased levels of hyperactive behaviors (inattention, impulsivity, and overactivity) (McCann et al., 2007). Other re-

▲ A child with ADHD is likely to behave inappropriately regardless of the setting.

search now points to the possible role of the pesticides found in foods as contributing to an increased risk of ADHD (Bouchard, Bellinger, Wright, & Weisskopf, 2010).

As you saw in the discussion of genetics, one of the more consistent findings among children with ADHD involves its association with maternal smoking. In addition, a variety of other pregnancy complications (for example, maternal alcohol consumption and low birth weight) may play a role in increasing the chance that a child with a genetic predisposition for ADHD will display the symptoms characteristic of this disorder (Barkley, 2006d). Unfortunately, many of the studies in this area confound socioeconomic and genetic factors (for example, there is an increased likelihood of smoking among women who also have low socioeconomic status), and there may not be a direct link between maternal smoking and ADHD (Lindblad & Hjern, 2010).

Psychological and social dimensions of ADHD may further influence the disorder itself—especially how the child fares over time. Negative responses by parents, teachers, and peers to the affected child's impulsivity and hyperactivity may contribute to feelings of low self-esteem, especially in children who are also depressed (Anastopoulos, Sommer, & Schatz, 2009). Years of constant reminders by teachers and parents to behave, sit quietly, and pay attention may create a negative self-image in these children, which, in turn, can negatively affect their ability to make friends. Thus, the possible biological influences on impulsivity, hyperactivity, and attention, combined with attempts to control these children, may lead to rejection and consequent poor self-image. An integration of the biological and psychological influences on ADHD suggests that both need to be addressed when designing effective treatments (Durand, in press-a).

### Treatment of ADHD

Treatment for ADHD has proceeded on two fronts: biological and psychosocial interventions. Typically, the goal of biological treatments is to reduce the children's impulsivity and hyperactivity and to improve their attentional skills. Psychosocial treatments generally focus on broader issues such as improving academic performance, decreasing disruptive behavior, and improving social skills. Although these two kinds of approaches have typically developed independently, recent efforts combine them to have a broader impact on people with ADHD.

The first types of medication used for children with ADHD were stimulants. Since the use of stimulant medication for children with ADHD was first described (Bradley, 1937), hundreds of studies have documented the effectiveness of this kind of medication in reducing the core symptoms (hyperactivity, impulsiveness) of the disorder. It is estimated that more than 2.5 million children in the United States are being treated with these medications (Centers for Disease Control and Prevention, 2005). Drugs such as methylphenidate (Ritalin, Metadate, Concerta) and D-amphetamine (Dexedrine, Dextrostat) have proved helpful for more than 70% of cases in at least temporarily reducing hyperactivity and impulsivity and improving concentration on tasks (Greenhill & Hechtman, 2009). Adderall, which is a longer-acting version of these psychostimulants, reduces the need for multiple doses for children during the day but has similar positive effects (Connor, 2006).

Originally, it seemed paradoxical or contrary to expect that children would calm down after taking a stimulant. However, on the same low doses, children and adults with and without ADHD react in the same way. It appears that stimulant medications reinforce the brain's ability to focus attention during problem-solving tasks (Connor, 2006). Although the use of stimulant medications remains controversial, especially for children, most clinicians recommend them temporarily, in combination with psychosocial interventions, to help improve children's social and academic skills.

The concerns over the use of stimulant medications now include their potential for abuse. In Chapter 11, we discussed that drugs such as Ritalin are sometimes abused for their ability to create elation and reduce fatigue (Setlik, Bond, & Ho, 2009). And, the widespread misperception that use of these prescription medications is harmless is also of great concern (Desantis & Hane, 2010). This is particularly worrisome for children with ADHD because they are at increased risk for later substance abuse (Wagner & Pliszka, 2009). A newer drug—atomoxetine (Strattera)—also appears effective for some children with ADHD, but it is a selective norepinephrine-reuptake inhibitor and therefore does not produce the same "highs" when used in larger doses. Research suggests that other drugs, such as some antidepressants (bupropion, imipramine) and a drug used for treating high blood pressure (clonidine), may have similar effects as Strattera on people with ADHD (Wagner & Pliszka, 2009). Not all children with ADHD have depression or high blood pressure (although depression can be a problem in some of these children), but these drugs work on the same neurotransmitter systems (norepinephrine and dopamine) involved in ADHD. All these drugs seem to improve compliance and decrease negative behaviors in many children, and their effects do not usually last when the drugs are discontinued.

Some portion of children with ADHD do not respond to medications, and most children who do respond show improvement in ability to focus their attention but do not show gains in the important areas of academics and social skills (Smith, Barkley, & Shapiro, 2006). In addition, the medications often result in unpleasant side effects, such as insomnia, drowsiness, or irritability (Kollins, 2008). Because of these findings, researchers have applied various behavioral interventions to help these children at home and in school (Ollendick & Shirk, in press; Ramsay, 2009). In general, the programs set such goals as increasing the amount of time the child remains seated, the number of math papers completed, or appropriate play with peers. Reinforcement programs reward the child for improvements and, at times, punish misbehavior with loss of rewards. Other programs incorporate parent training to teach families how to respond constructively to their child's behaviors and how to structure the child's day to help prevent difficulties (Ollendick & Shirk, in press). Social skills training for these children, which includes teaching them how to interact appropriately with their peers, also seems to be an important treatment component (de Boo & Prins, 2007). For adults with ADHD, cognitive-behavioral intervention to reduce distractibility and improve organizational skills appears quite helpful. Most clinicians typically recommend a combination of approaches designed to individualize treatments for those with ADHD, targeting both short-term management issues (decreasing hyperactivity and impulsivity) and long-term concerns (preventing and reversing academic decline and improving social skills).

To determine whether or not a combined approach to treatment is the most effective, a large-scale study initiated by the National Institute of Mental Health was conducted by six teams of researchers (Jensen et al., 2001). Labeled the Multimodal Treatment of Attention Deficit/Hyperactivity Disorder (MTA) study, this 14-month study included 579 children who were randomly assigned to one of four groups. One group of the children received routine care without medication or specific behavioral interventions (community care). The three treatment groups consisted of medication management (usually methylphenidate), intensive behavioral treatment, and a combination of the two treatments. Initial reports from the study suggested that the combination of behavioral treatments and medication, and medication alone, were superior to behavioral treatment alone and community intervention for ADHD symptoms. For problems that went beyond the specific symptoms of ADHD, such as social skills, academics, parent–child relations, oppositional behavior, and anxiety or depression, results suggested slight advantages of combination over single treatments (medication management, behavioral treatment) and community care.

Some controversy surrounds the interpretation of these findings—specifically, whether or not the combination of behavioral and medical treatments is superior to medication alone (Biederman, Spencer, Wilens, & Greene, 2001; Pelham, 1999). One of the concerns surrounding the study was that although medication continued to be dispensed, the behavioral treatment was faded over time, which may account for the observed differences.

Practically, if there is no difference between these two treatments, most parents and therapists would opt for simply providing medication for these children. As we mentioned previously, behavioral interventions have the added benefit of improving aspects of the child and family that are not directly affected by medication. Reinterpretations of the data from this large-scale study continue, and more research likely will be needed to clarify

## Innovative Approaches

### Helpful "Designer Drugs"

Get ready to learn a new word—*psychopharmacogenetics.*

Psychopharmacogenetics is the study of how your genetic makeup influences your response to certain drugs. The hope for this field is that medications can be matched or even "designed" for individuals to better complement their specific needs (Weinshilboum, 2003). For example, one study looked at the use of methylphenidate (Ritalin) for children and adolescents with ADHD (Polanczyk, Zeni, et al., 2007). For those who had a specific gene defect—the adrenergic alpha-2A receptor gene (ADRA2A)—methylphenidate had a strong positive effect, especially on their problems with inattention. This was not the case for those with ADHD who did not have the ADRA2A gene defect. Currently, the use of drug treatments tends to be by trial and error: A medication is attempted at a particular dose; if it is not effective, the dose is changed. If that does not work, a different medication is tried. This new study holds the promise of potentially eliminating this guesswork and tailoring the treatment to the individual.

This exciting new approach to medical treatment for mental illness brings with it some weighty concerns. Central to these concerns are issues of privacy and confidentiality. Genetic screening to identify defects is likely to identify any number of potential genetic problems in each of us. How will schools, employment sites, and insurance companies view this information if they have access? The concern is that people will be discriminated against based on this information (for example, having the genes that may or may not lead to having ADHD or another disorder). Will the desire to better target drug treatments outweigh these types of ethical concerns? Most new technical advances, like those promised with psychopharmacogenetics, also uncover new problems, and it is essential that ethical issues be part of the discussion as researchers move forward in this area.

the combined and separate effects of these two approaches to treatment (Ollendick & Shirk, in press). Despite these advances, however, children with ADHD continue to pose a considerable challenge to their families and to the educational system.

## Learning Disorders

Academic achievement is highly valued in our society. We often compare the performance of our schoolchildren with that of children in other cultures to estimate whether we are succeeding or failing as a world leader and economic force. On a personal level, because parents often invest a great deal of time, resources, and emotional energy to ensure their children's academic success, it can be extremely upsetting when a child with no obvious intellectual deficits does not achieve as expected. In this section, we describe **learning disorders** in reading, mathematics, and written expression—all characterized by performance that is substantially below what would be expected given the person's age, intelligence quotient (IQ) score, and education. We also look briefly at disorders that involve how we communicate. Consider the case of Alice.

### ALICE | *Taking a Reading Disorder to College*

Alice, a 20-year-old college student, sought help because of her difficulty in several of her classes. She reported that she had enjoyed school and had been a good student until about the sixth grade, when her grades suffered significantly. Her teacher informed her parents that she wasn't working up to her potential and she needed to be better motivated. Alice had always worked hard in school but promised to try harder. However, with each report card her mediocre grades made her feel worse about herself. She managed to graduate from high school, but by that time she felt she was not as bright as her friends.

Alice enrolled in the local community college and again found herself struggling with the work. Over the years, she had learned several tricks that seemed to help her study and at least get passing grades. She read the material in her textbooks aloud to herself; she had earlier discovered that she could recall the material much better this way than if she just read silently to herself. In fact, reading silently, she could barely remember any of the details just minutes later.

After her sophomore year, Alice transferred to the university, which she found even more demanding and where she failed most of her classes. After our first meeting, I suggested that she be formally assessed to identify the source of her difficulty. As suspected, Alice had a learning disability.

Scores from an IQ test placed her slightly above average, but she was assessed to have significant difficulties with reading. Her comprehension was poor, and she could not remember most of the content of what she read. We recommended that she continue with her trick of reading aloud, because her comprehension for what she heard was adequate. In addition, Alice was taught how to analyze her reading—that is, how to outline and take notes. She was even encouraged to audiotape her lectures and play them back to herself as she drove around in her car. Although Alice did not become an A student, she was able to graduate from the university, and she now works with young children who themselves have learning disabilities.

### *Clinical Description*

According to *DSM-IV-TR* criteria, Alice would be diagnosed as having a **reading disorder**, which is defined as a significant discrepancy between a person's reading achievement and what would be expected for someone of the same age—referred to by some as "unexpected underachievement" (Fletcher, Lyon, Fuchs, & Barnes, 2007). More specifically, the criteria require that the person read at a level significantly below that of a typical person of the same age, cognitive ability (as measured on an IQ test), and educational background. In addition, a diagnosis of reading disorder requires that the person's disability not be caused by a sensory difficulty, such as trouble with sight or hearing, and should not be the result of poor or absent instruction. Similarly, *DSM-IV-TR* defines a **mathematics disorder** as achievement below expected performance in mathematics and a **disorder of written expression** as achievement below expected performance in writing. In each of these disorders, the difficulties are sufficient to interfere with the students' academic achievement and to disrupt their daily activities.

There is some controversy over using the discrepancy between IQ and achievement as part of the process of identifying children with learning disorders. Part of the criticism involves the delay between when learning problems occur and when they finally result in a large enough difference between IQ scores and achievement scores—which may not be measurable until later in

**DSM-IV-TR**

**Table 14.2** Diagnostic Criteria for Learning Disorders*

for Reading Disorder (Developmental Reading Disorder), Mathematics Disorder (Developmental Arithmetic Disorder), and Disorder of Written Expression (Developmental Expressive Writing Disorder)

**A.** (Reading achievement) (Mathematical ability) (Writing skill), as measured by individually administered standardized tests, is substantially below that expected given the person's chronological age, measured intelligence, and age-appropriate education.

**B.** The disturbance in criterion A significantly interferes with academic achievement or activities of daily living that require (reading skills) (mathematical ability) (composition of written texts).

**C.** If a sensory deficit is present, the learning difficulties are in excess of those usually associated with it.

*The three separate learning disorders are combined here because the basic criteria are identical, with the exception of the specific ability that is affected.

a child's academic life. An alternative approach—called *response to intervention*—is now being used by many clinicians. It involves identifying a child as having a learning disorder when the response to a known effective intervention (for example, an early reading program) is significantly inferior to the performance by peers (Jackson, Pretti-Frontczak, Harjusola-Webb, Grisham-Brown, & Romani, 2009). This provides an early warning system and focuses on providing effective instruction.

### Statistics

Estimates of how prevalent learning disorders are range from 5% to 10% (Altarac & Saroha, 2007), although the frequency of this diagnosis appears to increase in wealthier regions of the country—suggesting that with better access to diagnostic services, more children are identified (see ■ Figure 14.1). It is currently believed that nearly 6 million children in the United States are diagnosed as having a specific learning disorder (Altarac & Saroha, 2007). There do appear to be racial differences in the diagnosis of learning disorders. Approximately 1% of white children and 2.6% of black children were receiving services for problems with learning in 2001 (Bradley, Danielson, & Hallahan, 2002). However, this research also suggests that the differences were related to the economic status of the child, not ethnic background.

Difficulties with reading are the most common of the learning disorders and occur in some form in 4% to 10% of the general population (Pennington & Bishop, 2009). Mathematics disorder appears in approximately 1% of the population (Tannock, 2009a), but there is limited information about the prevalence of disorder of written expression among children and adults. Early studies suggested that boys were more likely to have a reading disorder than girls, although more recent research indicates that boys and girls may be equally affected by this disorder (Feinstein & Phillips, 2006). Students with learning disorders are more likely to drop out of school (Vogel & Reder, 1998), more likely to be unemployed (Shapiro & Lentz, 1991), and more likely to have suicidal thoughts and attempt suicide (Daniel et al., 2006).

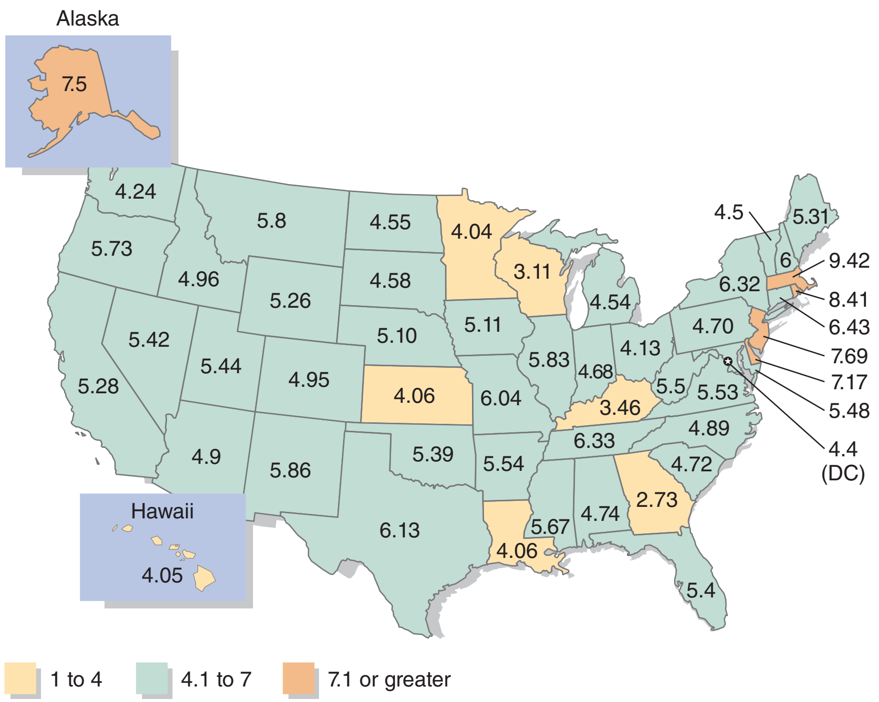
Interviews with adults who have learning disabilities reveal that their school experiences were generally negative and the effects often lasted beyond graduation. One man who did not have special assistance during school reports the following:

> I faked my way through school because I was very bright. I resent most that no one picked up my weaknesses. Essentially I judge myself on my failures. . . . [I] have always had low self-esteem. In hindsight I feel that I had low self-esteem in college. . . . I was afraid to know myself. A blow to my self-esteem when I was in school was that I could not write a poem or a story. . . . I could not write with a pen or pencil. The computer has changed my life. I do everything on my computer. It acts as my memory. I use it to structure my life and for all of my writing since my handwriting and written expression has always been so poor. (Polloway, Schewel, & Patton, 1992, p. 521)

A group of disorders loosely identified as verbal or *communication disorders* seems closely related to learning disorders. These disorders can appear deceptively benign, yet their presence early in life can cause wide-ranging problems later. For a brief overview of these disorders, which include **stuttering**, **expressive language disorder**, **selective mutism**, and **tic disorder**, see Table 14.1.

### Causes

Theories about the causes of learning disorders include genetic, neurobiological, and environmental factors. The genetic research in this area is particularly complex. It is clear that learning disorders run in families, and sophisticated family and twin studies bear this out (Fletcher et al., 2007). Yet, analyses of the genes involved suggest that many effects are not specific—meaning that there are not different genes responsible for reading disorders and mathematics disorders. Instead, there are genes that affect learning and they may contribute to problems across domains (reading, mathematics, writing) (Plomin & Kovas, 2005).



**■ FIGURE 14.1** Uneven distribution. The highest percentages of schoolchildren diagnosed with learning disabilities are in the wealthiest states.

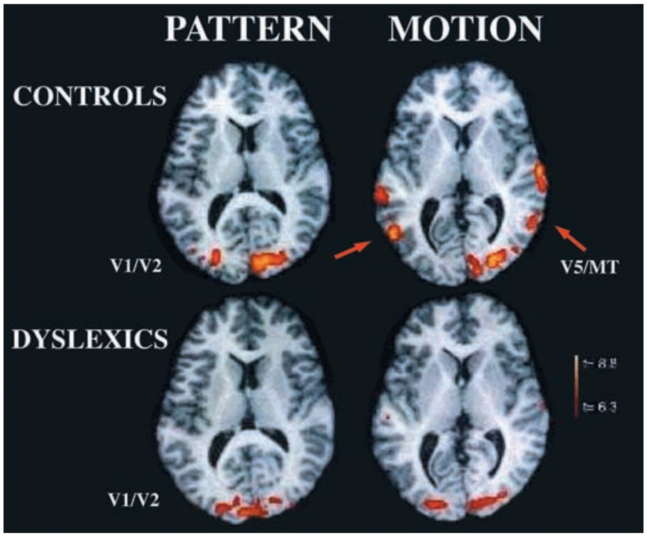
The different problems associated with learning themselves have different origins. For example, children (and adults) often have very different problems associated with reading. Reading disorders are sometimes broken into problems with word recognition (difficulty decoding single words—sometimes called *dyslexia*), fluency (problems being able to read words and sentences smoothly and automatically), and comprehension (difficulty getting meaning from what is read) (Tannock, 2009b). Most research to date focuses on problems with word recognition, and there is evidence that some develop these problems primarily through their genes whereas others develop

**TABLE 14.1** Communication and Related Disorders

| Disorder | Clinical Description | Statistics | Causes | Treatments |
|---|---|---|---|---|
| STUTTERING | A disturbance in speech fluency—repeating syllables or words, prolonging certain sounds, making obvious pauses, or substituting words to replace ones that are difficult to articulate. | Occurs twice as often among boys as among girls. Begins most often in children under the age of 3, and 98% of cases occur before the age of 10. Approximately 80% of children who stutter before they enter school will no longer stutter after they have been in school a year or so (Kroll & Beitchman, 2009). | Multiple brain pathways appear to be involved, and genetic influences may be a factor (Kroll & Beitchman, 2009). | Regulated-breathing method—the person is instructed to stop speaking when a stuttering episode occurs and then to take a deep breath (exhale, then inhale) before proceeding (Bothe, Davidow, Bramlett, & Ingham, 2006). Altered auditory feedback (electronically changing speech feedback to people who stutter) (Lincoln, Packman, & Onslow, 2006). Forms of self-monitoring, in which people modify their own speech for the words they stutter (Venkatagiri, 2005). |
| EXPRESSIVE LANGUAGE DISORDERS | Limited speech in *all* situations. *Expressive language* (what is said) is significantly below *receptive language* (what is understood); the latter is usually average. | Occurs in 10% to 15% of children younger than 3 years of age and is almost five times as likely to affect boys as girls (Koyama, Beitchman, & Johnson, 2009). | An unfounded psychological explanation is that the children's parents may not speak to them enough. A biological theory is that middle ear infection is a contributory cause. | May be self-correcting and may not require special intervention. |
| SELECTIVE MUTISM | Persistent failure to speak in specific situations—such as school—despite the ability to do so (Kearney, 2010). | Occurs in less than 1% of children and most often between the ages of 5 and 7. More prevalent among girls than boys. | Not much is known. Anxiety is one possible cause (Bergman & Lee, 2009). | *Contingency management:* Giving children praise and reinforcers for speaking while ignoring their attempts to communicate in other ways. Reinforcing successive approximations to speaking (Bergman & Lee, 2009). |
| TIC DISORDERS | Involuntary motor movements *(tics),* such as head twitching, or vocalizations, such as grunts, that often occur in rapid succession, come on suddenly, and happen in idiosyncratic or stereotyped ways. In one type, *Tourette's disorder,* vocal tics often include the involuntary repetition of obscenities. | Of all children, up to 20% show some tics during their growing years, and 1 to 10 children out of every 1,000 have Tourette's disorder (Jummani & Coffey, 2009). Usually develops before the age of 14. High comorbidity between tics and ADHD, as well as obsessive-compulsive disorder (Jummani & Coffey, 2009). | There are likely multiple vulnerability genes that influence the form and severity of tics (Jummani & Coffey, 2009). | *Psychological:* Self-monitoring, relaxation training, and habit reversal. *Pharmacological:* haloperidol; more recently, risperidone and ziprasidone. |

problems as a result of environmental factors (Shaywitz, Mody, & Shaywitz, 2006). Genes located on chromosomes 1, 2, 3, 6, 11, 12, 15, and 18 have all been repeatedly linked to these difficulties (Tannock, 2009b). At the same time, environmental influences such as the home reading habits of families can significantly affect outcomes—especially with skills such as word recognition—suggesting that reading to children at risk for reading disorders can lessen the impact of the genetic influence (Petrill, Deater-Deckard, Thompson, DeThorne, & Schatschneider, 2006).

Various forms of subtle brain impairment have also been thought responsible for learning disabilities; some of the earliest theories involve a neurological explanation (Hinshelwood, 1896). Research suggests structural, as well as functional, differences in the brains of people with learning disabilities. Specifically, three areas of the left hemisphere appear to be involved in problems with dyslexia (word recognition)—Broca's area (which affects articulation and word analysis), an area in the left parietotemporal area (which affects word analysis), and an area in the left occipitotemporal area (which affects recognizing word form) (Shaywitz et al., 2006). A different area in the left hemisphere—the intraparietal sulcus—seems to be critical for the development of a sense of numbers and is implicated in mathematics disorder (Fletcher et al., 2007). In contrast, there is no current evidence for specific deficits responsible for disorders of written expression.



Courtesy National Institutes of Mental Health

▲ These functional MRI scans of composite data from six dyslexic adults and eight controls show a horizontal slice through the brain, with the face at the top. Imaging shows atypical brain activity associated with dyslexia. The scans were performed while subjects tracked a pattern of moving dots on a computer screen. A brain area (V5/MT) normally active during such motion tasks did not switch on in dyslexic subjects (right). Their brain activity was more similar to that of controls during a pattern recognition task (left).

Disorders of reading have been diagnosed more often in English-speaking countries. Although some have thought that this may simply be a difference in diagnostic practices, biological research now suggests it may involve the relative complexity of the written word in English. Researchers tested individuals who displayed reading disorders and who spoke English, French, or Italian (Paulesu et al., 2001). Although those who spoke Italian did better on tests of reading, brain imaging (positron emission tomography) while all participants were reading indicated each of these people with reading disorders experienced the same reduced activity in the left temporal lobe. It was hypothesized that characteristics of the English language may make it a more difficult language to read, thus accounting for these cultural differences in rates of diagnosis for reading disorders.

You saw that Alice persisted despite the obstacles caused by her learning disorder, as well as by the reactions of teachers and others. What helped her continue toward her goal when others choose, instead, to drop out of school? Psychological and motivational factors that have been reinforced by others seem to play an important role in the eventual outcome of people with learning disorders. Factors such as socioeconomic status, cultural expectations, parental interactions and expectations, and child management practices, together with existing neurological deficits and the types of support provided in the school, seem to determine outcome (Tannock, 2009b).

### *Treatment of Learning Disorders*

As you will see in the case of intellectual disability, learning disorders primarily require educational intervention. Biological (drug) treatment is typically restricted to those individuals who may also have ADHD, which as we discussed involves impulsivity and an inability to sustain attention and can be helped with certain stimulant medications, such as methylphenidate (Ritalin). Educational efforts can be broadly categorized into (1) specific skills instruction, including instruction on vocabulary, finding the main idea, and finding facts in readings, and (2) strategy instruction, which includes efforts to improve cognitive skills through decision making and critical thinking (Fletcher et al., 2007).

Many programs are used to assist children with their problems related to learning. One approach that has received considerable research support is called Direct Instruction (Coyne et al., 2009). This program includes several components; among them are systematic instruction (using highly scripted lesson plans that place students together in small groups based on their progress) and teaching for mastery (teaching students until they understand all concepts). In addition, children are constantly assessed and plans are modified based on progress or lack of progress. Direct Instruction and several related training programs appear to significantly improve academic skills in children with learning disorders (Coyne et al., 2009).

▲ Specially designed computer games may help children with learning disorders improve their language skills.

How do these behavioral and educational approaches help children with reading difficulties? Are they just tricks or adaptations to learning, or do these treatments have a more profound effect on the way these children process information? Exciting research using brain-imaging technology is allowing us to answer these important questions. One study used functional magnetic resonance imaging scanning (fMRI) to compare how children with and without reading disorders processed simple tasks (Temple et al., 2003). The children with reading difficulties were then exposed to 8 weeks of intensive training on a computer program that helped them work on their auditory and language-processing skills. Not only did the children improve their reading skills, but their brains started functioning in a way similar to the brains of their peers who were good readers. This and similar studies (Keller & Just, 2009) mirror results seen with other disorders—namely, that behavioral interventions can change the way the brain works and that we can use such interventions to help individuals with significant problems.

## Concept Check 14.1

Assign a label to each of the following cases: (a) ADHD, (b) attention deficit disorder without hyperactivity, (c) selective mutism, (d) Tourette's disorder, or (e) reading disorder.

1. Ten-year-old Cole can be frustrating to his parents, teachers, and friends. He has trouble waiting his turn during games and does things seemingly without thinking. He often calls out answers in school, sometimes before the complete question is asked. ____________
2. At home, 6-year-old Miley has been excitedly telling her cousins about a recent trip to the beach. This would surprise her teachers, who have never heard her speak. ____________
3. Eleven-year-old Jonathan is frequently off-task at school. He works quickly, makes careless mistakes, and he appears not to listen when someone else is speaking. He often forgets to bring his homework to school and typically comes home without his assignment folder. ____________
4. Trent's developmental disorder is characterized by uncontrollable yelps, sniffs, and grunting noises. ____________
5. Kelly was a good student until the sixth grade. Her grades slowly began to drop, despite her increased studying. Now, as a high school senior concerned about graduation, and with hopes of going to college, Kelly has sought help. She places above average on an IQ test but shows significant problems with reading and comprehension. ____________
6. Eight-year-old Chandra is described by everyone as a "handful." She fidgets constantly in class, drumming her fingers on the desk, squirming in her chair, and getting up and down. She has trouble waiting her turn at work or at play, and she sometimes has violent outbursts. ____________

# Pervasive Developmental Disorders

People with **pervasive developmental disorders** all experience problems with language, socialization, and cognition (Durand, in press-a). The word *pervasive* means that these problems are not relatively minor but significantly affect individuals throughout their lives. Included under the heading of pervasive developmental disorders are autistic disorder (or autism), Asperger's disorder, **Rett's disorder**, **childhood disintegrative disorder**, and **pervasive developmental disorder not otherwise specified**. We focus on two of the more prevalent pervasive developmental disorders—autistic disorder and Asperger's disorder; the other disorders are highlighted in Table 14.2. Note that discussions are under way to possibly reorganize these disorders under the title "autism spectrum disorders" in *DSM-5;* this spectrum of disorders would include autistic disorder (autism), Asperger's disorder, childhood disintegrative disorder, and pervasive developmental disorder not otherwise specified (American Psychiatric Association, 2010a).

## Autistic Disorder

**Autistic disorder (autism)** is a childhood disorder characterized by significant impairment in social interactions and communication and by restricted patterns of behavior, interest, and activities (Durand, in press-a). Individuals with this disorder have a puzzling array of symptoms. Consider the case of Amy.

### AMY | *In Her Own World*

Amy, 3 years old, spends much of her day picking up pieces of lint. She drops the lint in the air and then watches intently as it falls to the floor. She also licks the back of her hands and stares at the saliva. She hasn't spoken yet and can't feed or dress herself. Several times a day she screams so loudly that the neighbors at first thought she was being abused. She doesn't seem to be interested in her mother's love and affection but will take her mother's hand to lead her to the refrigerator. Amy likes to eat butter—whole pats of it, several at a time. Her mother uses the pats of butter that you get at some restaurants to help Amy learn and to keep her well-behaved. If Amy helps with dressing herself, or if she sits quietly for several minutes, her mother gives her some butter. Amy's mother knows that the butter isn't good for her, but it is the only thing that seems to get through to the child. The family's pediatrician has been concerned about Amy's developmental delays for some time and has recently suggested that she be evaluated by specialists. The pediatrician thinks Amy may have autism and the child and her family will probably need extensive support.

### *Clinical Description*

Three major characteristics of autism are expressed in *DSM-IV-TR:* impairment in social interactions, impairment in communication, and restricted behavior, interests, and activities (American Psychiatric Association, 2000).

**TABLE 14.2** Additional Pervasive Developmental Disorders

| Disorder | Clinical Description | Statistics | Causes | Treatments |
|---|---|---|---|---|
| RETT'S DISORDER | A progressive neurological disorder that primarily affects girls. Includes constant hand-wringing, increasingly severe intellectual disability, and impaired motor skills, *after* typical development (Sigafoos et al., 2009). Motor skills deteriorate over time; social skills develop typically at first, decline between the ages of 1 and 3, and then partially improve. May be removed from *DSM-5* because it is minimally related to autism. | Rett's disorder is relatively rare, occurring in approximately 1 per 12,000 to 15,000 live female births. | A mutation of a gene on the X chromosome (MECP2) appears responsible for over 80% of cases (Toth & King, 2010). | Focuses on teaching self-help and communication skills and on efforts to reduce problem behaviors (Sigafoos et al., 2009). |
| CHILDHOOD DISINTEGRATIVE DISORDER | Involves severe regression in language, adaptive behavior, and motor skills after a 2- to 4-year period of normal development (Volkmar et al., 2009). | Rare, occurring in 1 of approximately every 100,000 births. | Although no specific cause has been identified, several factors suggest an accumulation of a number of rare genetic mutations (Volkmar et al., 2009). | Typically involves behavioral interventions to regain lost skills and behavioral and pharmacological treatments to help reduce behavioral problems. |
| PERVASIVE DEVELOPMENTAL DISORDER NOT OTHERWISE SPECIFIED | Severe and pervasive impairments in social interactions but without all criteria for autistic disorder. These individuals may not display the early avoidance of social interaction but still may exhibit significant social problems. Their problems may become more obvious after 3 years of age. | Little good evidence for prevalence at this time, although appears more common than autistic disorder. | Some of the same genetic influences and neurobiological impairments common in autism are likely involved in these individuals as well (Volkmar et al., 2009). | Focuses on teaching socialization and communication skills and on efforts to reduce problem behaviors. |

**Impairment in Social Interactions** One of the defining characteristics of people with autistic disorder is that they do not develop the types of social relationships expected for their age (Volkmar, Klin, Schultz, & State, 2009). Amy never made friends among her peers and often limited her contact with adults to using them as tools—for example, taking the adult's hand to reach for something she wanted. For young children, the signs of social problems usually include a failure to engage in skills such as joint attention (Dawson et al., 2004; MacDonald et al., 2006). When sitting with a parent in front of a favorite toy, young children will typically look back and forth between the parent and the toy, smiling, in an attempt to engage the parent with the toy. However, this skill in joint attention is noticeably absent in children with autism.

Research using sophisticated eye-tracking technology shows how this social awareness problem evolves as the children grow older. In one study, scientists showed an adult man with autism scenes from some movies and compared how he looked at social scenes with how a man without autism did so (Klin, Jones, Schultz, Volkmar, & Cohen, 2002). You can see from the photo that the man with autism (indicated by the red lines) scanned nonsocial aspects of the scene (the actors' mouth and jacket), while the man without autism looked at the socially meaningful sections (looking from eye to eye of the people conversing). This research suggests that people with autism—for reasons not yet fully understood—may not be interested in social situations and therefore may not enjoy meaningful relationships with others or have the ability to develop them.

**Impairment in Communication** People with autism nearly always have severe problems with communicating. About one-third never acquire speech (Tager-Flusberg et al., 2009). In those with some speech, much of their communication is unusual. Some repeat the speech of others, a pattern called echolalia we referred to earlier as a sign of delayed speech development. If you say, "My name is Eileen, what's yours?" they will repeat all or part of what you said: "Eileen, what's yours?" And often, not only are your words repeated, but so is your intonation. Some people with autism who can speak are unable or unwilling to carry on conversations with others.

Image not available due to copyright restrictions

**Restricted Behavior, Interests, and Activities** The more striking characteristics of autism include *restricted patterns of behavior, interests,* and *activities.* Amy appeared to like things to stay the same: She became extremely upset if even a small change was introduced (such as moving her toys in her room). This intense preference for the status quo has been called *maintenance of sameness.* Often, people with autism spend countless hours in *stereotyped and ritualistic behaviors,* making such stereotyped movements as spinning around in circles, waving their hands in front of their eyes with their heads cocked to one side, or biting their hands (Durand, in press-a).

**DSM-IV-TR**

### **Table 14.3** Diagnostic Criteria for Autistic Disorder

**A.** A total of six (or more) items from (1), (2), and (3), with at least two from (1) and one each from (2) and (3):
  **1.** Qualitative impairment in social interaction, as manifested by at least two of the following:
    **a.** Marked impairment in the use of multiple nonverbal behaviors such as eye-to-eye gaze, facial expression, body postures, and gestures to regulate social interaction
    **b.** Failure to develop peer relationships appropriate to developmental level
    **c.** A lack of spontaneous seeking to share enjoyment, interests, or achievements with other people (e.g., by a lack of showing, bringing, or pointing out objects of interest)
    **d.** Lack of social or emotional reciprocity
  **2.** Qualitative impairments in communication as manifested by at least one of the following:
    **a.** Delay in, or total lack of, the development of spoken language (not accompanied by an attempt to compensate through alternative modes of communication such as gesture or mime)
    **b.** In individuals with adequate speech, marked impairment in the ability to initiate or sustain a conversation with others
    **c.** Stereotyped and repetitive use of language or idiosyncratic language
    **d.** Lack of varied, spontaneous make-believe play or social imitative play appropriate to developmental level
  **3.** Restricted repetitive and stereotyped patterns of behavior, interests, and activities, as manifested by at least one of the following:
    **a.** Encompassing preoccupation with one or more stereotyped and restricted patterns of interest that is abnormal in either intensity or focus
    **b.** Apparently inflexible adherence to specific, nonfunctional routines or rituals
    **c.** Stereotyped and repetitive motor mannerisms (e.g., hand or finger flapping or twisting, or complex whole-body movements)
    **d.** Persistent preoccupation with parts of objects
**B.** Delays or abnormal functioning in at least one of the following areas, with onset prior to age 3 years: (1) social interaction, (2) language as used in social communication, or (3) symbolic or imaginative play.
**C.** The disturbance is not better accounted for by Rett's disorder or childhood disintegrative disorder.

### *Statistics*

Autism was once thought to be a rare disorder, although more recent estimates of its occurrence seem to show an increase in its prevalence. Previous estimates found a rate of 2 to 20 per 10,000 people, although it is now believed to be as high as 1 in every 500 births (Shattuck, 2006). The prevalence of autism spectrum disorders (which include autistic disorder, pervasive developmental disorder not otherwise specified, and Asperger's disorder) is estimated as high as 1 in every 110 births (Centers for Disease Control and Prevention, 2009). This rise in the rates may be the result of increased awareness on the part of professionals who now distinguish the pervasive developmental disorders from intellectual disability. However, other environmental factors (such as exposure to toxic chemicals) cannot as yet be ruled out as contributing to this rise.

Gender differences for autism vary depending on the IQ level of the person affected. For people with IQs under 35, autism is more prevalent among females; in the higher IQ range, it is more prevalent among males. The reason for these differences is not known (Centers for Disease Control and Prevention, 2009). Autistic disorder appears to be a universal phenomenon, identified in every part of the world, including Sweden (Gillberg, 1984), Japan (Sugiyama & Abe, 1989), Russia (Lebedinskaya & Nikolskaya, 1993), and China (Chung, Luk, & Lee, 1990). Most people with autism develop the associated symptoms before the age of 36 months (American Psychiatric Association, 2000).

People with autism have a range of IQ scores. Earlier estimates placed the rate of intellectual disability among children with autism as high as 75%, although more recent work—using more appropriate tests for these children—indicates the range between 40% and 55% (Chakrabarti & Fombonne, 2001; Edelson, 2006). This means that 45% to 60% of people with autism have average or above average IQs.

IQ measures are used to determine prognosis: The higher children score on IQ tests, the less likely they are to need extensive support by family members or people in the helping professions. Conversely, young children with autistic disorder who score poorly on IQ tests are more likely to be severely delayed in acquiring communication skills and to need a great deal of educational and social support as they grow older. Usually, language abilities and IQ scores are reliable predictors of how children with autistic disorder will fare later in life: the better the language skills and IQ test performance, the better the prognosis (Ben Itzchak, Lahat, Burgin, & Zachor, 2008).

### *Causes: Psychological and Social Dimensions*

Autism is a puzzling condition, so you should not be surprised to find numerous theories of why it develops. One theory is that autistic disorder probably does not have a single cause (Durand, in press-a; Volkmar et al., 2009). Instead, a number of biological contributions may combine with psychosocial influences to result in the unusual behaviors of people with autism. Because historical context is important to research, it is helpful to examine past, as well as more recent, theories of autism. (In doing this, we are departing from this book's usual format of providing biological dimensions first.)

Historically, autistic disorder was seen as the result of failed parenting (Bettelheim, 1967; Ferster, 1961; Tinbergen & Tinbergen, 1972). Mothers and fathers of children with autism were characterized as perfectionistic, cold, and aloof (Kanner, 1949), with relatively high socioeconomic status (Allen, DeMyer, Norton, Pontius, & Yang, 1971; Cox, Rutter, Newman, & Bartak, 1975) and higher IQs than the general population (Kanner, 1943). Descriptions such as these have inspired theories holding parents responsible for their children's unusual behaviors. These views were devastating to a generation of parents, who felt guilty and responsible for their children's problems. Imagine being accused of such coldness toward your own child as to cause serious and permanent disabilities. More sophisticated research using larger samples of children and families suggests that the parents of individuals with autism may not differ substantially from parents of children without disabilities (Bhasin & Schendel, 2007).

**Autism: Christina**

*"Last year she used (the communication book) a lot more in communicating with us. We have different pictures in the book. They're called picture symbols to represent what she might want, what she might need, what she's asking of us."*

**Go to Psychology CourseMate at www.cengagebrain.com to watch this video.**

Other theories about the origins of autism were based on the unusual speech patterns of some individuals—namely, their tendency to avoid first-person pronouns such as *I* and *me* and to use *he* and *she* instead. For example, if you ask a child with autism, "Do you want something to drink?" he might say, "He wants something to drink" (meaning "I want something to drink"). This observation led some theorists to wonder whether autism involves a lack of self-awareness (Goldfarb, 1963; Mahler, 1952). Imagine, if you can, not understanding that your existence is distinct. There is no "you," only "them." Such a debilitating view of the world was used to explain the unusual ways people with autism behaved. Theorists suggested that the withdrawal seen among people with autistic disorder reflected a lack of awareness of their own existence.

However, later research has shown that some people with autistic disorder do seem to have self-awareness (Lind & Bowler, 2009) and that it follows a developmental progression. Just like children without a disability, those with cognitive abilities below the level expected for a child of 18 to 24 months show little or no self-recognition, but people with more advanced abilities do demonstrate self-awareness. Self-concept may be lacking when people with autism also have cognitive disabilities or delays, not because of autism itself.

Myths about people with autism are perpetuated when the idiosyncrasies of the disorder are highlighted. These perceptions are furthered by portrayals such as Dustin Hoffman's in *Rain Man*—his character could, for instance, instantaneously and accurately count hundreds of toothpicks falling to the floor. This type of ability—referred to as savant skills—is just not typical with autism. It is important always to separate myth from reality and to be aware that such portrayals do not accurately represent the full range of manifestations of this complex disorder.

The phenomenon of echolalia, repeating a word or phrase spoken by another person, was once believed to be an unusual characteristic of this disorder. Subsequent work in developmental psychopathology, however, has demonstrated that repeating the speech of others is part of the normally developing language skills observed in most young children (Dawson, Mottron, & Gernsbacher, 2008). Even a behavior as disturbing as the self-injurious behavior sometimes seen in people with autism is observed in milder forms, such as head banging, among typically developing infants (de Lissovoy, 1961). This type of research has helped clinicians isolate the facts from the myths about autism and clarify the role of development in the disorder. One generally accepted conclusion is that social deficiencies are the primary distinguishing characteristic of people with autism.

### Causes: Biological Dimensions

At present, few workers in the field of autism believe that psychological or social influences play a major role in the development of this disorder. To the relief of many families, it is now clear that poor parenting is not responsible for autism. Deficits in such skills as socialization and communication appear to be biological in origin. Biological theories about the origins of autism, examined next, have received much empirical support.

**Genetic Influences** It is now clear that autism has a genetic component (Volkmar, Klin, & Schultz, 2005). Families that have one child with autism have a 5% to 10% risk of having another child with the disorder. This rate is 50 to 200 times the risk in the general population, providing strong evidence of a genetic component in the disorder. The exact genes involved in the development of autism remain elusive. There is evidence for some involvement with numerous chromosomes, and work is ongoing in this complex field (Autism Genome Project Consortium, 2007). One area that is receiving attention involves the genes responsible for the brain chemical oxytocin. Because oxytocin is shown to have a role in how we bond with others and in our social memory, researchers are looking for whether genes responsible for this neurochemical are involved with the disorder. Preliminary work identifies an association between autism and an oxytocin receptor gene (Wermter et al., 2010), and researchers expect more connections will be identified in the coming years.

▲ Temple Grandin has a Ph.D. in animal science and a successful career designing humane equipment for handling livestock. She also has autism.

**Neurobiological Influences** As in the area of genetics, many neurobiological influences are being studied to help explain the social and communication problems observed in autism (Volkmar et al., 2009). One intriguing theory involves research on the amygdala—the area of the brain that, as you saw in Chapter 5, is involved in emotions such as anxiety and fear. Researchers studying the brains of people with autism after they died note that adults with and without the disorder have amygdalae of about the same size but that those with autism have fewer neurons in this structure (Schumann & Amaral, 2006). Earlier research showed that young children with autism actually have a larger amygdala. The theory being proposed is that the amygdala in children with autism is enlarged early in life—causing excessive anxiety and fear (perhaps contributing to their social withdrawal). With continued stress, the release of the stress hormone cortisol damages the amygdala, causing the relative absence of these neurons in adulthood. The damaged amygdala may account for the different way people with autism respond to social situations (Lombardo, Chakrabarti, & Baron-Cohen, 2009).

An additional neurobiological influence we mentioned in the section on genetics involves the neuropeptide oxytocin. Remember that this is an important social neurochemical that influences bonding and is found to increase trust and reduce fear. Some research on children with autism found lower levels of oxytocin in their blood (Modahl et al., 1998), and giving people with autism oxytocin improved their ability to remember and process information with emotion content (such as remembering happy faces), a problem that is symptomatic of autism (Guastella et al., 2010). This is one of a number of theories being explored as possible contributors to this puzzling disorder.

▲ Timothy plays violin and piano, as well as baseball. Autistic disorder occurs in all cultures and races.

One highly controversial theory is that mercury—specifically, the mercury previously used as a preservative in childhood vaccines (thimerosal)—is responsible for the increases seen in autism over the last decade. Large epidemiological studies conducted in Denmark show that there is no increased risk of autism in children who are vaccinated (Madsen et al., 2002; Parker, Schwartz, Todd, & Pickering, 2004). Despite this and other convincing evidence, the correlation between when a child is vaccinated for measles, mumps, and rubella (12–15 months) and when the symptoms of autism first become evident (before 3 years), continues to fuel the belief by many families that there must be some connection.

The study of autism is a relatively young field and still awaits an integrative theory of how biological, psychological, and social factors work together to put an individual at risk for developing autism. It is likely, however, that further research will identify the biological mechanisms that may explain the social aversion experienced by many people with the disorder. Also to be outlined are the psychological and social factors that interact early with the biological influences, producing deficits in socialization and communication, as well as the characteristic unusual behaviors.

## Asperger's Disorder

**Asperger's disorder** involves a significant impairment in the ability to engage in meaningful social interaction, along with restricted and repetitive stereotyped behaviors but without the severe delays in language or other cognitive skills characteristic of people with autism (American Psychiatric Association, 2000). First described by Hans Asperger in 1944, it was Lorna Wing in the early 1980s who recommended that Asperger's disorder be reconsidered as a separate disorder from autism, with an emphasis on the unusual and limited interests (such as train schedules) displayed by these individuals (Volkmar et al., 2009).

### Clinical Description

People with this disorder display impaired social relationships and restricted or unusual behaviors or activities (such as following airline schedules or memorizing ZIP codes), but unlike individuals with autism, they can often be quite verbal. This tendency to be much more interested in esoteric facts than in people, along with their often formal and academic style of speech, has led some to refer to the disorder as the "little professor syndrome." Individuals with Asperger's disorder show few severe cognitive impairments and usually have IQ scores within the average range (Volkmar et al., 2009). They often exhibit clumsiness and poor coordination. Some researchers think Asperger's disorder may be a milder form of autism rather than a separate disorder.

What must it be like to have this disorder? Is it an exquisite solitude, divorced from the stressors of modern life? Or is it an oppressive state of anxiety, filled with the need to try constantly to maintain sameness in a chaotic world? Such fundamental questions have led some researchers to interview these individuals, hoping to gain a better understanding of the disorder so as to aid those who have it. This is just one statement that reflects the highly logical and factual nature of the way people with Asperger's disorder think:

> My name is Robert Edwards. I am an intelligent, unsociable but adaptable person. I would like to dispel any untrue rumors about me. I am not edible. I cannot fly. I cannot use telekinesis. My brain is not large enough to destroy the entire world when unfolded. I did not teach my long-haired guinea pig, Chronos, to eat everything in sight (that is the nature of the long-haired guinea pig). (Volkmar et al., 2005, p. 3179)

**DSM-IV-TR** **Table 14.4** Diagnostic Criteria for Asperger's Disorder

**A.** Qualitative impairment in social interaction, as manifested by at least two of the following:
   **1.** Marked impairment in the use of multiple nonverbal behaviors such as eye-to-eye gaze, facial expression, body postures, and gestures to regulate social interaction
   **2.** Failure to develop peer relationships appropriate to developmental level
   **3.** A lack of spontaneous seeking to share enjoyment, interests, or achievements with other people (e.g., by a lack of showing, bringing, or pointing out objects of interest to other people)
   **4.** Lack of social or emotional reciprocity

**B.** Restricted repetitive and stereotyped patterns of behavior, interests, and activities, as manifested by at least one of the following:
   **1.** Encompassing preoccupation with one or more stereotyped and restricted patterns of interest that is abnormal either in intensity or focus
   **2.** Apparently inflexible adherence to specific, nonfunctional routines or rituals
   **3.** Stereotyped and repetitive motor mannerisms (e.g., hand or finger flapping or twisting, or complex whole-body movements)
   **4.** Persistent preoccupation with parts of objects

**C.** The disturbance causes clinically significant impairment in social, occupational, or other important areas of functioning.

**D.** There is no clinically significant delay in cognitive development or in the development of age-appropriate self-help skills, adaptive behavior (other than in social interaction), and curiosity about the environment in childhood.

**E.** Criteria are not met for another specific pervasive developmental disorder or schizophrenia.

As researchers gain access to more of these accounts, understanding of Asperger's disorder should grow, allowing greater assistance to those with this disorder.

### Statistics

Until recently, most diagnosticians were relatively unfamiliar with Asperger's disorder, and it is generally believed that many individuals with the disorder went undiagnosed. Current estimates of the prevalence are between 1 and 2 per 10,000, and it is believed to occur more often in boys than in girls (Volkmar et al., 2009).

### Causes

Little research about the causes of Asperger's disorder exists, although a possible genetic contribution is suspected. Asperger's disorder does seem to run in families, and there appears to be a higher prevalence of both autism and Asperger's disorder in some families. Because of the social–emotional disturbances observed in people with this disorder, as you just saw with autism, researchers are looking at the amygdala for its possible role in the cause (Schultz, Romanski, & Tsatsanis, 2000), although to date there is no conclusive evidence for a specific biological or psychological model.

## Treatment of Pervasive Developmental Disorders

Most treatment research has focused on children with autism, so we primarily discuss treatment research for these individuals. However, because treatment for all of the pervasive developmental disorders relies on a similar approach, this research should be relevant across disorders. One generalization that can be made about autism, as well as the other pervasive developmental disorders, is that no completely effective treatment exists. Attempts to eliminate the social problems experienced by these individuals have not been successful to date. Rather, like the approach to individuals with intellectual disability, most efforts at treating people with pervasive developmental disorders focus on enhancing their communication and daily living skills and on reducing problem behaviors, such as tantrums and self-injury (Durand, in press-a). We describe some of these approaches next, including work on early intervention for young children with autism.

### Psychosocial Treatments

Early psychodynamic treatments were based on the belief that autism is the result of improper parenting, and they encouraged ego development (the creation of a self-image) (Bettelheim, 1967). Given our current understanding about the nature of the disorder, we should not be surprised to learn that treatments based solely on ego development have not had a positive impact on the lives of people with autism (Kanner & Eisenberg, 1955). Greater success has been achieved with behavioral approaches that focus on skill building and behavioral treatment of problem behaviors. This approach is based on the early work of Charles Ferster and Ivar Lovaas. Although the work of Ferster and Lovaas has been greatly refined over the past 30 years, the basic premise—that people with autism can learn and that they can be taught some skills they lack—remains central. There is a great deal of overlap between the treatment of autism and the treatment of intellectual disability. With that in mind, we highlight several treatment areas that are particularly important for people with autism, including communication and socialization.

Problems with communication and language are among the defining characteristics of this disorder. People with autism often do not acquire meaningful speech; they tend either to have limited speech or to use unusual speech, such as echolalia. Teaching people to speak in a useful way is difficult. Think about how we teach languages: It mostly involves imitation. Imagine how you would teach a young girl to say the word *spaghetti*. You could wait for several days until she said a word that sounded something like *spaghetti* (maybe *confetti*) and then reinforce her. You could then spend several days or weeks trying to shape *confetti* into something closer to *spaghetti*. Or you could just prompt, "Say 'spaghetti.'" Fortunately, most children can imitate and learn to communicate efficiently. But a child who has autism can't or won't imitate.

In the mid-1960s, the late Ivar Lovaas and his colleagues took a monumental first step toward addressing the difficulty of getting children with autism to respond. They used the basic behavioral procedures of shaping and discrimination training to teach these nonspeaking children to imitate others verbally (Lovaas, Berberich, Perloff, & Schaeffer, 1966). The first skill the researchers taught the children was to imitate other people's speech. They began by reinforcing a child with food and praise for making any sound while watching the teacher. After the child mastered that step, they reinforced the child only if she made a sound after the teacher made a request—such as the phrase, "Say 'ball'" (a procedure known as *discrimination training*). Once the child reliably made some sound after the teacher's request, the teacher used *shaping* to reinforce only approximations of the requested sound, such as the sound of the letter "b." Sometimes the teacher helped the child with physical prompting—in this case, by gently holding the lips together to help the child make the sound of "b." Once the child responded successfully, a second word was introduced—such as "mama"—and the procedure was repeated. This continued until the child could correctly respond to multiple requests, demonstrating imitation by copying the words or phrases made by the teacher. Once the children could imitate, speech was easier, and progress was made in teaching some of them to use labels, plurals, sentences, and other more complex forms of language (Lovaas, 1977). Despite the success of some children in learning speech, other children do not respond to this training, and workers sometimes use alternatives to vocal speech, such as sign language and devices that have vocal output and can literally "speak" for the child (Tager-Flusberg et al., 2009).

One of the most striking features of people with autism is their unusual reactions to other people. Although social deficits are among the more obvious problems experienced by people with autism, they can also be the most difficult to teach. A number of approaches are now used to teach social skills (for example, how to carry on a conversation and ask questions of other people), including the use of peers who do not have autism as trainers, and there is evidence that those with autism can improve their socialization skills (e.g., Cotugno, 2009).

Lovaas and his colleagues at the University of California, Los Angeles, reported on their early intervention efforts with young children (Lovaas, 1987). They used intensive behavioral treatment for communication and social skills problems for 40 hours or more per week, which seemed to improve intellectual and educational functioning. Follow-up suggests that these improvements are long lasting (McEachin, Smith, & Lovaas, 1993). These studies created considerable interest, as well as controversy. Some critics question the research on practical, as well as experimental, grounds, claiming that one-on-one therapy for 40 hours per week was too expensive and time consuming; they also criticized the studies for having no proper control group. Nevertheless, the findings from this important work and a number of replications around the world suggest that early intervention is promising for children with autism (Eldevik et al., 2009).

### Biological Treatments

No one medical treatment has been found to cure autism. In fact, medical intervention has had little success on the core symptoms of social and language difficulties. A variety of pharmacological treatments are used to decrease agitation, and the major tranquilizers and serotonin-specific reuptake inhibitors seem helpful here (Volkmar et al., 2009).

Because autism may result from a variety of deficits, it is unlikely that one drug will work for everyone with this disorder. Much current work is focused on finding pharmacological treatments for specific behaviors or symptoms.

### Integrating Treatments

The treatment of choice for people with pervasive developmental disorder—including autism and Asperger's disorder—combines various approaches to the many facets of this disorder. For children, most therapy consists of school education with special psychological supports for problems with communication and socialization. Behavioral approaches have been most clearly documented as benefiting children in this area. Pharmacological treatments can help some of them temporarily. Parents also need support because of the great demands and stressors involved in living with and caring for such children. As children with autism grow older, intervention focuses on efforts to integrate them into the community, often with supported living arrangements and work settings. Because the range of abilities of people with autism is so great, however, these efforts differ dramatically. Some people are able to live in their own apartments with only minimal support from family members. Others, with more severe forms of cognitive impairment, require more extensive efforts to support them in their communities.

### Concept Check 14.2

Determine how well you are able to diagnose the disorder in each of the following situations by labeling them (a) autistic disorder, (b) Asperger's disorder, (c) Rett's disorder, (d) childhood disintegrative disorder, or (e) pervasive developmental disorder.

1. Six-year-old Tangelique has a low IQ and enjoys sitting in the corner by herself, where she arranges her toys or spins around in circles. She is unable to communicate verbally. She throws temper tantrums when her routine is changed even in the slightest way or when her parents try to get her to do something she doesn't want to do. ____________
2. At an early age, Dwight became preoccupied with geography and could name all of the state capitals. His speech development was not delayed but he does not like to play with other children or to be touched or held. ____________
3. Five-year-old Alicia has increasingly severe intellectual disability and is beginning to have trouble walking on her own. One of the characteristics of her disorder is constant hand-wringing. ____________
4. Once Rolondo turned 5, his parents noticed that his motor skills and language abilities were beginning to regress dramatically. ____________
5. Six-year-old Megan doesn't entirely avoid social interactions, but she experiences many problems in communicating and dealing with people. ____________

## Intellectual Disability

**Intellectual disability (ID)** (previously referred to as mental retardation) is a disorder evident in childhood as significantly below-average intellectual and adaptive functioning (Toth & King, 2010).

©John M. Heller/Getty Images

▲ Lauren Potter (an actress with Down syndrome) plays "Becky Jackson" in the popular television show Glee.

People with intellectual disability experience difficulties with day-to-day activities to an extent that reflects both the severity of their cognitive deficits and the type and amount of assistance they receive. Perhaps more than any other group you have studied in this text, people with intellectual disability have throughout history received treatment that can best be described as shameful (Scheerenberger, 1983). With notable exceptions, societies throughout the ages have devalued individuals whose intellectual abilities are deemed less than adequate. Although *DSM-IV-TR* uses the term "mental retardation," we use "intellectual disability" throughout this chapter to be consistent with changes in terminology in this field and possible changes in *DSM-5* (American Psychiatric Association, 2010b).

The field of intellectual disability has undergone dramatic and fundamental changes during the past two decades. What it means to have an intellectual disability, how to define it, how to label it, and how people with this disorder are treated have been scrutinized, debated, and fought over by a variety of concerned groups. We describe the disorder in the context of these important changes, explaining both the status of people who have intellectual disabilities and our current understanding of its causes and treatment.

The manifestations of intellectual disability are varied. Some individuals function quite well, even independently, in our complex society. For example, Chris Burke (an actor with Down syndrome) was the first actor with an intellectual disability to star in a television series (*Life Goes On*) and also appeared on *Touched by an Angel*. Also, Lauren Potter (another actor with Down syndrome) played a cheerleader in the television show *Glee*. Others with intellectual disability have significant cognitive and physical impairments and require considerable assistance to carry on day-to-day activities. Consider the case of James.

### JAMES | *Up to the Challenge*

James's mother contacted us because he was disruptive at school and at work. James was 17 and attended the local high school. He had Down syndrome and was described as likable and, at times, mischievous. He enjoyed skiing, bike riding, and many other activities common among teenage boys. His desire to participate was a source of some conflict between him and his mother: he wanted to take the driver's education course at school, which his mother felt would set him up for failure, and he had a girlfriend he wanted to date, a prospect that also caused his mother concern.

School administrators complained because James didn't participate in activities such as physical education, and at the work site that was part of his school program he was often sullen, sometimes lashing out at the supervisors. They were considering moving him to a program with more supervision and less independence.

James's family had moved often during his youth, and they experienced striking differences in the way each community responded to James and his intellectual disability. In some school districts, he was immediately placed in classes with other children his age and his teachers were provided with additional assistance and consultation. In others, it was just as quickly recommended that he be taught separately. Sometimes the school district had a special classroom in the local school for children with intellectual disability. Other districts had programs in other towns, and James would have to travel an hour to and from school each day. Every time he was assessed in a new school, the evaluation was similar to earlier ones. He received scores on his IQ tests in the range of 40 to 50, which placed him in the moderate range of intellectual disability. Each school gave him the same diagnosis: Down syndrome with moderate intellectual disability. At each school, the teachers and other professionals were competent and caring individuals who wanted the best for James and his mother. Yet some believed that to learn skills James needed a separate program with specialized staff. Others felt they could not provide a program with specialized staff. Still others felt they could provide a comparable education in a regular classroom and that to have peers without disabilities would be an added benefit.

In high school, James had several academic classes in a separate classroom for children with learning problems, but he participated in some classes, such as gym, with students who did not have intellectual disability. His current difficulties in gym (not participating) and at work (being oppositional) were jeopardizing his placement in both programs. When I spoke with James's mother, she expressed frustration that the work program was beneath him because he was asked to do boring, repetitious work such as folding paper. James expressed a similar frustration, saying that he was treated like a baby. He could communicate fairly well when he wanted to, although he sometimes would become confused about what he wanted to say and it was difficult to understand everything he tried to articulate. On observing him at school and at work, and after speaking with his teachers, we realized that a common paradox had developed. James resisted work he thought was too easy. His teachers interpreted his resistance to mean that the work was too hard for him, and they gave him even simpler tasks. He resisted or protested more vigorously, and they responded with even more supervision and structure.

## Clinical Description

People with intellectual disability display a broad range of abilities and personalities. Individuals like James, who have mild or moderate impairments, can, with proper preparation, carry out

**DSM-IV-TR** **Table 14.5** Diagnostic Criteria for Intellectual Disability (Mental Retardation)

**A.** Significantly subaverage intellectual functioning: an IQ of approximately 70 or below on an individually administered IQ test (for infants, a clinical judgment of significantly subaverage intellectual functioning).

**B.** Concurrent deficits or impairments in present adaptive functioning (i.e., the person's effectiveness in meeting the standards expected for his or her age by his or her cultural group) in at least two of the following areas: communication, self-care, home living, social/interpersonal skills, use of community resources, self-direction, functional academic skills, work, leisure, health, and safety.

**C.** The onset is before age 18 years.

Code based on degree of severity reflecting level of intellectual impairment:

Mild intellectual disability: IQ level 50–55 to approximately 70

Moderate intellectual disability: IQ level 35–40 to 50–55

Severe intellectual disability: IQ level 20–25 to 35–40

Profound intellectual disability: IQ level below 20 or 25

Intellectual disability, severity unspecified: When there is strong presumption of intellectual disability but the person's intelligence is untestable by standard tests

*Source:* Reprinted, with permission, from American Psychiatric Association. (2000). *Diagnostic and statistical manual of mental disorders* (4th ed., text revision). Washington, DC: Author, © 2000 American Psychiatric Association.

most of the day-to-day activities expected of any of us. Many can learn to use mass transportation, purchase groceries, and hold a variety of jobs. Those with more severe impairments may need help to eat, bathe, and dress themselves, although with proper training and support they can achieve a degree of independence. These individuals experience impairments that affect most areas of functioning. Language and communication skills are often the most obvious. James was only mildly impaired in this area, needing help with articulation. In contrast, people with more severe forms of intellectual disability may never learn to use speech as a form of communication, requiring alternatives such as sign language or special communication devices to express even their most basic needs. Because many cognitive processes are adversely affected, individuals with intellectual disability have difficulty learning, the level of challenge depending on how extensive the cognitive disability is.

Before examining the specific criteria for intellectual disability, note that, like the personality disorders we described in Chapter 12, intellectual disability is included on Axis II of *DSM-IV-TR.* Remember that separating disorders by axes serves two purposes: first, indicating that disorders on Axis II tend to be more chronic and less amenable to treatment, and second, reminding clinicians to consider whether these disorders, if present, are affecting an Axis I disorder. People can be diagnosed on both Axis I (for example, generalized anxiety disorder) and Axis II (for example, mild intellectual disability).

The *DSM-IV-TR* criteria for intellectual disability are in three groups. First, a person must have *significantly subaverage intellectual functioning,* a determination made with one of several IQ tests with a cutoff score set by *DSM-IV-TR* of approximately 70. Roughly 2% to 3% of the population score at 70 or below on these tests. The American Association on Intellectual and Developmental Disabilities (AAIDD), which has its own, similar definition of intellectual disability, has a cutoff score of approximately 70 to 75 (Thompson et al., 2009; Toth & King, 2010).

The second criterion of both the *DSM-IV-TR* and the AAIDD definitions for intellectual disability calls for *concurrent deficits or impairments in adaptive functioning.* In other words, scoring "approximately 70 or below" on an IQ test is not sufficient for a diagnosis of intellectual disability; a person must also have significant difficulty in at least two of the following areas: communication, self-care, home living, social and interpersonal skills, use of community resources, self-direction, functional academic skills, work, leisure, health, and safety. To illustrate, although James had many strengths, such as his ability to communicate and his social and interpersonal skills (he had several good friends), he was not as proficient as other teenagers at caring for himself in areas such as home living, health, and safety or in academic areas. This aspect of the definition is important because it excludes people who can function quite well in society but for various reasons do poorly on IQ tests. For instance, someone whose primary language is not English may do poorly on an IQ test but may still function at a level comparable to peers. This person would not be considered to have intellectual disability even with a score of below 70 on the English-based IQ test.

The final criterion for intellectual disability is the *age of onset.* The characteristic below-average intellectual and adaptive abilities must be evident before the person is 18. This cutoff is designed to identify affected individuals when the brain is developing and therefore when any problems should become evident. The age criterion rules out the diagnosis of intellectual disability for adults who suffer from brain trauma or forms of dementia that impair their abilities. The age of 18 is somewhat arbitrary, but it is the age at which most children leave school, when our society considers a person an adult.

The imprecise definition of intellectual disability brings up an important issue: Intellectual disability, perhaps more than any of the other disorders, is defined by society. The cutoff score of 70 or 75 is based on a statistical concept (two or more standard deviations from the mean), not on qualities inherent in people who supposedly have intellectual disability. There is little disagreement about the diagnosis for people with the most severe disabilities; however, the majority of people diagnosed with intellectual disability are in the mild range of cognitive impairment. They need some support and assistance, but remember that the criteria for using the label of intellectual disability are based partly on a somewhat arbitrary cutoff score for IQ that can (and does) change with changing social expectations.

People with intellectual disability differ significantly in their degree of disability. Almost all classification systems have differentiated these individuals in terms of their ability or on the cause of the intellectual disability (Toth & King, 2010). Traditionally (and still evident in the *DSM-IV-TR*), classification systems have identified four levels of intellectual disability: *mild,* which is identified by an IQ score between 50–55 and 70; *moderate,* with a range of 35–40 to 50–55; *severe,* ranging from 20–25 to 35–40; and *profound,* which includes people with IQ scores below 20–25. It is difficult to categorize each level of intellectual disability

▲ Although he cannot speak, this man is learning to communicate with an eye-gaze board, pointing to or simply looking at the image that conveys his message.

according to "average" individual achievements by people at each level. A person with severe or profound intellectual disability tends to have extremely limited formal communication skills (no spoken speech or only one or two words) and may require great or even total assistance in dressing, bathing, and eating. Yet people with these diagnoses have a range of skills that depend on training and the availability of other supports. Similarly, people like James, who have mild or moderate intellectual disability, should be able to live independently or with minimal supervision; again, however, their achievement depends partly on their education and the community support available to them.

Perhaps the most controversial change being suggested in the new AAIDD definition of intellectual disability is its description of different levels of this disorder, which are based on the level of support or assistance people need: *intermittent, limited, extensive,* or *pervasive* (Thompson et al., 2009). The important difference is that the AAIDD system identifies the role of "needed supports" in determining level of functioning, whereas *DSM-IV-TR* implies that the ability of the person is the sole determining factor. The AAIDD system focuses on specific areas of assistance a person needs that can then be translated into training goals. Whereas his *DSM-IV-TR* diagnosis might be "moderate intellectual disability," James might receive the following AAIDD diagnosis: "a person with intellectual disability who needs limited supports in home living, health and safety, and in academic skills." The AAIDD definition emphasizes the types of support James and others require, and it highlights the need to identify what assistance is available when considering a person's abilities and potential. However, at this writing, the AAIDD system has not been assessed empirically to determine whether it has greater value than traditional (*DSM*) systems.

An additional method of classification has been used in the educational system to identify the abilities of students with intellectual disability. It relies on three categories: *educable intellectual disability* (based on an IQ of 50 to approximately 70–75), *trainable intellectual disability* (IQ of 30 to 50), and *severe intellectual disability* (IQ below 30) (Cipani, 1991). The assumption is that students with educable intellectual disability (comparable to mild intellectual disability) could learn basic academic skills; students with trainable intellectual disability (comparable to moderate intellectual disability) could not master academic skills but could learn rudimentary vocational skills; and students with severe intellectual disability (comparable to severe and profound intellectual disability) would not benefit from academic or vocational instruction. Built into this categorization system is the automatic negative assumption that certain individuals cannot benefit from certain types of training. This system and the potentially stigmatizing and limiting *DSM-IV-TR* categories (mild, moderate, severe, and profound intellectual disability) inspired the AAIDD categorization of needed supports. Current trends are away from the educational system of classification, because it inappropriately creates negative expectations in teachers. Clinicians continue to use the *DSM-IV-TR* system; time will tell whether the AAIDD categories will be widely adopted.

▲ Intellectual disability can be defined in terms of the level of support people need.

### Statistics

Approximately 90% of people with intellectual disability fall under the label of mild intellectual disability (IQ of 50 to 70). When you add individuals with moderate, severe, and profound intellectual disability (IQ below 50), the total population of people with this disorder represents 1% to 3% of the general population (Toth & King, 2010).

The course of intellectual disability is chronic, meaning that people do not go through periods of remission, such as with substance use disorders or anxiety disorders. However, the prognosis for people with this disorder varies considerably. Given appropriate training and support, individuals with less severe forms of intellectual disability can live relatively independent and productive lives. People with more severe impairments require more assistance to participate in work and community life.

Over the last century, a curious thing has occurred—IQ scores have risen. This phenomenon is known as the Flynn effect (Flynn, 1984). As these scores rise, those who make up IQ tests adjust the assessments every decade or two to keep the average score around 100. For most people, these changes have no practical effect. However, for people hovering at the cutoff point for intellectual disability, this may mean the difference between receiving the diagnosis or not (Durand & Christodulu, 2006). In one study, the number of people scoring just below 70 (the cutoff for mild intellectual disability) tripled when they were administered one of the revised IQ tests (Kanaya, Scullin, & Ceci, 2003). These results emphasize the caution we need to take when interpreting who does or does not have intellectual disability.

## Causes

There are literally hundreds of known causes of intellectual disability, including the following:

*Environmental:* For example, deprivation, abuse, and neglect
*Prenatal:* For instance, exposure to disease or drugs while still in the womb
*Perinatal:* Such as difficulties during labor and delivery
*Postnatal:* For example, infections and head injury

As we mentioned in Chapter 11, heavy use of alcohol among pregnant women can produce a disorder in their children called *fetal alcohol syndrome,* a condition that can lead to severe learning disabilities. Other prenatal factors that can produce intellectual disability include the pregnant woman's exposure to disease and chemicals and poor nutrition. In addition, lack of oxygen (anoxia) during birth and malnutrition and head injuries during the developmental period can lead to severe cognitive impairments. Despite the large number of known causes of intellectual disability, it's important to remember one fact: Nearly 25% of cases either cannot be attributed to any known cause or are thought to be the result of social and environmental influences (Toth & King, 2010).

### *Biological Dimensions*

Most research on the causes of intellectual disability focuses on biological influences. We next look at biological dimensions that appear to be responsible for the more common forms of intellectual disability.

**Genetic Influences** Almost 300 genes have been identified as having the potential to contribute to intellectual disability, and it is expected that there are many more (Inlow & Restifo, 2004). A portion of the people with more severe intellectual disability have identifiable single-gene disorders, involving a *dominant gene* (expresses itself when paired with a normal gene), a *recessive gene* (expresses itself only when paired with another copy of itself), or an *X-linked gene* (present on the X or sex chromosome).

Only a few dominant genes result in intellectual disability, probably because of natural selection: someone who carries a dominant gene that results in intellectual disability is less likely to have children and thus less likely to pass the gene to offspring. Therefore, this gene becomes less likely to continue in the population. However, some people, especially those with mild intellectual disability, do marry and have children, thus passing on their genes. One example of a dominant gene disorder, *tuberous sclerosis,* is relatively rare, occurring in 1 of approximately every 30,000 births. About 60% of the people with this disorder have intellectual disability, and most have seizures (uncontrolled electrical discharges in the brain) and characteristic bumps on the skin that during their adolescence resemble acne (Curatolo, Bombardieri, & Jozwiak, 2008).

The next time you drink a diet soda, notice the warning, "Phenylketonurics: Contains Phenylalanine." This is a caution for people with the recessive disorder called **phenylketonuria (PKU)**, which affects 1 of every 14,000 newborns and is characterized by an inability to break down a chemical in our diets called phenylalanine. Until the mid-1960s, the majority of people with this disorder had intellectual disability, seizures, and behavior problems, resulting from high levels of this chemical. However, researchers developed a screening technique that identifies the existence of PKU; infants are now routinely tested at birth, and any individuals identified with PKU can be successfully treated with a special diet that avoids the chemical phenylalanine. This is a rare example of the successful prevention of one form of intellectual disability.

Because untreated maternal PKU can harm the developing fetus, there is concern now that women with PKU who are of childbearing age may not stick to their diets and inadvertently cause PKU-related intellectual disability in their children before birth. Many physicians recommend dietary restriction through the person's lifetime, and especially during the childbearing period—thus the warnings on products with phenylalanine (Widaman, 2009).

**Lesch-Nyhan syndrome**, an X-linked disorder, is characterized by intellectual disability, signs of cerebral palsy (spasticity or tightening of the muscles), and self-injurious behavior, including finger and lip biting (Nyhan, 1978). Only males are affected, because a recessive gene is responsible; when it is on the X chromosome in males, it does not have a normal gene to balance it because males do not have a second X chromosome. Women with this gene are carriers and do not show any of the symptoms.

As our ability to detect genetic defects improves, more disorders will be identified genetically. The hope is that our increased knowledge will be accompanied by improvements in our ability to treat or, as in the case of PKU, prevent intellectual disability and other negative outcomes.

**Chromosomal Influences** It was only about 50 years ago that the number of chromosomes—46—was correctly identified in human cells (Tjio & Levan, 1956). Three years later, researchers found that people with Down syndrome (the disorder James displayed) had an additional small chromosome (Lejeune, Gauthier, & Turpin, 1959). Since that time, a number of other chromosomal aberrations that result in intellectual disability have been identified. We describe

### Lauren: A Kindergartner with Down Syndrome

*"The speech has been the most difficult . . . and communication naturally just causes tremendous behavior difficulties. . . . If there is not a way for her to communicate to us what her needs are and how she's feeling . . . it really causes a lot of actual shutdowns with Lauren. . . . She knows exactly what she wants and she is going to let you know even though she can't verbalize it."*

**Go to Psychology CourseMate at www.cengagebrain.com to watch this video.**

Down syndrome and fragile X syndrome in some detail, but there are hundreds of other ways in which abnormalities among the chromosomes can lead to intellectual disability.

**Down syndrome**, the most common chromosomal form of intellectual disability, was first identified by the British physician Langdon Down in 1866. Down had tried to develop a classification system for people with intellectual disability based on their resemblance to people of other races; he described individuals with this particular disorder as "mongoloid" because they resembled people from Mongolia (Scheerenberger, 1983). The term *mongoloidism* was used for some time but has been replaced with the term *Down syndrome.* The disorder is caused by the presence of an extra 21st chromosome and is therefore sometimes referred to as *trisomy 21.* For reasons not completely understood, during cell division two of the 21st chromosomes stick together (a condition called nondisjunction), creating one cell with one copy that dies and one cell with three copies that divide to create a person with Down syndrome.

People with Down syndrome have characteristic facial features, including folds in the corners of their upwardly slanting eyes, a flat nose, and a small mouth with a flat roof that makes the tongue protrude somewhat. Like James, they tend to have congenital heart malformations. Tragically, adults with Down syndrome have a greatly increased risk of dementia of the Alzheimer's type, a degenerative brain disorder that causes impairments in memory and other cognitive disorders (Wiseman, Alford, Tybulewicz, & Fisher, 2009). This disorder among people with Down syndrome occurs earlier than usual (sometimes in their early 20s) and has led to the finding that at least one form of Alzheimer's disease is attributable to a gene on the 21st chromosome.

The incidence of children born with Down syndrome has been tied to maternal age: As the age of the mother increases, so does her chance of having a child with this disorder (see ■ Figure 14.2). A woman at age 20 has a 1 in 2,000 chance of having a child with Down syndrome, at the age of 35 this risk increases to 1 in 500, and at the age of 45 it increases again to 1 in 18 births (Girirajan, 2009). Despite these numbers, many more children with Down syndrome are born to younger mothers simply because younger mothers have more children. The reason for the rise in incidence with maternal age is not clear. Some suggest that because a woman's ova (eggs) are all produced in youth, the older ones have been exposed to toxins, radiation, and other harmful substances over longer periods. This exposure may interfere with the normal meiosis (division) of the chromosomes, creating an extra 21st chromosome (Pueschel & Goldstein, 1991). Others believe the hormonal changes that occur as women age are responsible for this error in cell division (Crowley, Hayden, & Gulati, 1982).

For some time, it has been possible to detect the presence of Down syndrome—but not the degree of intellectual disability—through **amniocentesis**, a procedure that involves removing and testing a sample of the fluid that surrounds the fetus in the amniotic sac, and through **chorionic villus sampling (CVS)** in which a small piece of placenta tissue is removed and tested. These types of test are not always desirable because it is an invasive procedure (inserting a needle that could cause unwanted damage to the developing fetus). Fortunately, there are now more sophisticated tests of a mother's blood that can be used to detect Down syndrome as early as the first trimester of pregnancy (Schmitz, Netzer, & Henn, 2009).

**Fragile X syndrome** is a second common chromosomally related cause of intellectual disability (Toth & King, 2010). As its name suggests, this disorder is caused by an abnormality on the X chromosome, a mutation that makes the tip of the chromosome look as though it were hanging from a thread, giving it the appearance of fragility. As with Lesch-Nyhan syndrome, which also involves the X chromosome, fragile X primarily affects males because they do not have a second X chromosome with a normal gene to balance out the mutation. Unlike Lesch-Nyhan carriers, however, women who carry fragile X syndrome commonly display mild to severe learning disabilities (Koukoui & Chaudhuri, 2007). Men with the disorder display moderate to severe levels of

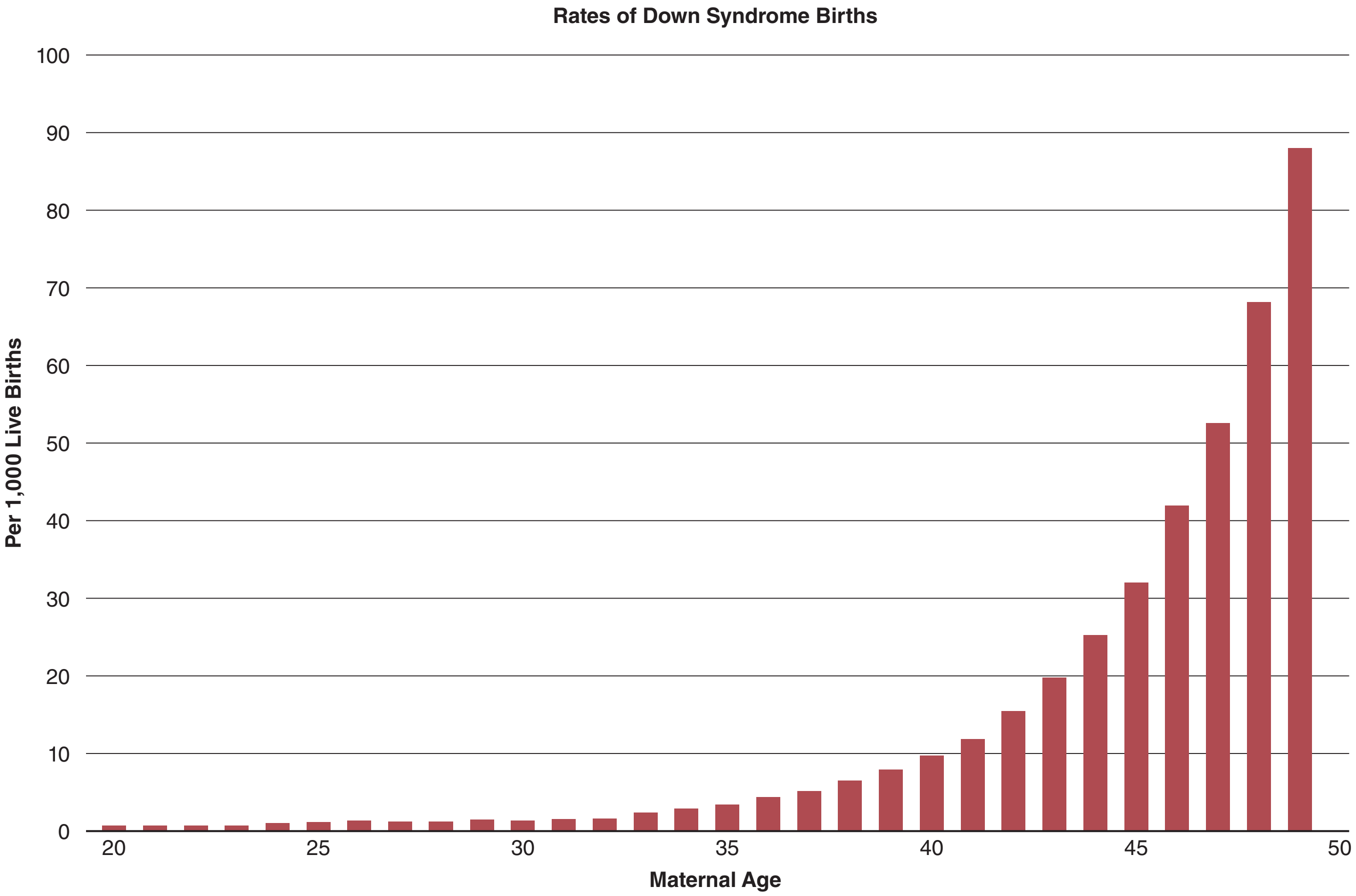
▲ An adult with Down syndrome.



■ **FIGURE 14.2** The increasing likelihood of Down syndrome with maternal age. (Based on data from Hook, E. B. (1982). Epidemiology of Down syndrome. In S. M. Pueschel & J. E. Rynders, Eds., *Down syndrome: Advances in biomedicine and the behavioral sciences* [pp. 11–88]. Cambridge, MA: Ware Press, © 1982 Ware University Press.)

intellectual disability and have higher rates of hyperactivity, short attention spans, gaze avoidance, and perseverative speech (repeating the same words again and again). In addition, such physical characteristics as large ears, testicles, and head circumference are common. Estimates are that 1 of every 4,000 males and 1 of every 8,000 females are born with fragile X syndrome (Toth & King, 2010).

### *Psychological and Social Dimensions*

Up to 25% of the cases of intellectual disability fall in the mild range and are not associated with any obvious genetic or physical disorders. Sometimes referred to as **cultural–familial intellectual disability**, people with these characteristics are thought to have cognitive impairments that result from a combination of psychosocial and biological influences, although the specific mechanisms that lead to this type of intellectual disability are not yet understood. The cultural influences that may contribute to this condition include abuse, neglect, and social deprivation.

It is sometimes useful to consider people with intellectual disability in two distinct groups: those with cultural–familial and those with biological (or "organic") forms of intellectual disability. People in the latter group have more severe forms of intellectual disability that are usually traceable to known causes such as fragile X syndrome. ■ Figure 14.3 shows that the cultural–familial group is composed primarily of individuals at the lower end of the IQ continuum (in other words, just part of the normal distribution), whereas in the organic group, genetic, chromosomal, and other factors affect intellectual performance which explains the "bump" in their numbers at that end of the distribution. The organic group increases the number of people at the lower end of the IQ continuum so that it exceeds the expected rate for a normal distribution (Toth & King, 2010).

## Treatment of Intellectual Disability

Biological treatment of intellectual disability is currently not a viable option. Generally, the treatment of individuals with intellectual disability parallels that of people with pervasive developmental disorders, attempting to teach them the skills they need to become more productive and independent. For individuals with mild intellectual disability, intervention is similar to that for people with learning disorders. Specific learning deficits are identified and addressed to help the student improve such skills as reading and writing. At the same time, these individuals often need additional support to live in the community. For people with more severe disabilities, the general goals are the same; however, the level of assistance they need is often more extensive. Remember that the expectation for all people with intellectual disability

▲ Amniocentesis can detect the presence of Down syndrome in a fetus. Guided by an ultrasound image, the doctor withdraws amniotic fluid for analysis.

is that they will in some way participate in community life, attend school and later hold a job, and have the opportunity for meaningful social relationships. Advances in electronic and educational technologies have made this goal realistic even for people with profound intellectual disability.

Individuals with intellectual disability can acquire skills through the many behavioral innovations first introduced in the early 1960s to teach such basic self-care as dressing, bathing, feeding, and toileting to people with even the most severe disabilities (Durand, in press-a). The skill is broken into its component parts (a procedure called a *task analysis*), and people are taught each part in succession until they can perform the whole skill. Performance on each step is encouraged by praise and by access to objects or activities the people desire (reinforcers). Success in teaching these skills is usually measured by the level of independence people can attain by using them. Typically, most individuals, regardless of their disability, can be taught to perform some skills.

Communication training is important for people with intellectual disability. Making their needs and wants known is essential for personal satisfaction and for participation in most social activities. The goals of communication training differ, depending on the existing skills. For people with mild levels of intellectual disability, the goals may be relatively minor (for example, improving articulation) or more extensive (for example, organizing a conversation) (Sigafoos, Arthur-Kelly, & Butterfield, 2006). Some, like James, have communication skills that are already adequate for day-to-day needs.

For individuals with the most severe disabilities, communication skills training can be particularly challenging, because they may have multiple physical or cognitive deficits that make spoken communication difficult or impossible. Creative researchers, however, use alternative systems that may be easier for these individuals, including the sign language, used primarily by people with hearing disabilities, and *augmentative communication strategies.* Augmentative strategies may use picture books, teaching the person to make a request by pointing to a picture—for instance, pointing to a picture of a cup to request a drink (Sigafoos et al., 2009). A variety of computer-assisted devices can be programmed so that the individual presses a button to produce complete spoken sentences (for example, "Would you come here? I need your help."). People with limited communication skills can be taught to use these devices, which helps them reduce the frustration of not being able to relate their feelings and experiences to other people (Durand, in press-b).

Concern is often expressed by parents, teachers, and employers that some people with intellectual disability can be physically or verbally aggressive or may hurt themselves. Considerable debate has ensued over the proper way to reduce these behavior problems; the most heated discussions involve whether to use painful punishers (Repp & Singh, 1990). Alternatives to punishment that may be equally effective in reducing behavior problems such as aggression and self-injury (Durand, in press-b) include teaching people how to communicate their need or desire for such things as attention that they seem to be getting with their problem behaviors. Important advances are being made in significantly reducing even severe behavior problems for some people.

In addition to ensuring that people with intellectual disability are taught specific skills, caretakers focus on the important task of

▲ The Illinois Asylum for Feeble-Minded Children, about 1880. Today, great efforts are made to keep children with intellectual disability in their homes and communities.

©Research Collections/University Archive/Lovejoy Library

supporting them in their communities. "Supported employment" involves helping an individual find and participate satisfactorily in a competitive job (Hall, Butterworth, Winsor, Gilmore, & Metzel, 2007). Research has shown not only that people with intellectual disability can be placed in meaningful jobs but also that, despite the costs associated with supported employment, it can be cost-effective (Sandys, 2007). The benefits to people who achieve the satisfaction of being a productive part of society are incalculable.

There is general agreement about *what* should be taught to people with intellectual disability. The controversy in recent years has been over *where* this teaching should take place. Should people with intellectual disability, especially the severe forms, be taught in specially designed separate classrooms or workshops, or should they attend their neighborhood public schools and work at local businesses? Increasingly, teaching strategies to help these students learn are being used in regular classrooms and in preparing them to work at jobs in the community (Frankel & Gold, 2007). There is at present no cure for intellectual disability, but the current prevention and treatment efforts suggest that meaningful changes can be achieved in the lives of those with intellectual disability.

## Prevention of Developmental Disorders

Prevention efforts for the developmental disorders outlined in this chapter are in their early stages of development. One such effort—early intervention—has been described for the pervasive developmental disorders and appears to hold considerable promise for some children. In addition, early intervention can target and assist children who, because of inadequate environments, are at risk for developing cultural–familial intellectual disability (Eldevik, Jahr, Eikeseth, Hastings, & Hughes, 2010). The national Head Start program is one such effort at early intervention; it combines educational, medical, and social supports for these children and their families. One project identified a group of children shortly after birth and provided them with an intensive preschool program, along with medical and nutritional supports. This intervention continued until the children began formal education in kindergarten (Martin, Ramey, & Ramey, 1990). The researchers of this study found that for all but one of the children in a control group who received medical and nutritional support but not the intensive educational experiences, each had IQ scores below 85 at age 3, but that 3-year-olds in the experimental group all tested above 85. Such findings are important because they show the potential for creating a lasting impact on the lives of children with developmental disorders and their families (Engle et al., 2007).

Although it appears that many children can make significant progress if interventions are initiated early in life (Eldevik et al., 2010), a number of important questions remain regarding early intervention efforts. Not all children, for example, benefit significantly from such efforts, and future research will need to resolve a number of lingering concerns. For example, researchers need to determine how best to identify children and families who will benefit from such programs, how early in the child's development programs should begin, and how long to continue these early intervention programs to produce desirable outcomes.

Given recent advances in genetic screening and technology, it may someday be possible to detect and correct genetic and chromosomal abnormalities; related ongoing research could fundamentally change our approach to children with developmental disorders. For example, one study used mice that were genetically engineered to model fragile X syndrome found in many individuals with intellectual disability (Suvrathan, Hoeffer, Wong, Klann, & Chattarji, in press). Researchers found that they could improve the functioning of certain glutamate receptors in the amygdala of the mice with a drug that blocks these receptors. The results were more normalized functioning between these neurons, a potential early medical intervention for children with fragile X disorder (Suvrathan et al., in press). Someday, it may be possible for similar research to be performed prenatally on children identified as having syndromes associated with intellectual disability. For example, it may soon be possible to conduct prenatal gene therapy, where a developing fetus that has been screened for a genetic disorder may be the target of intervention before birth (Ye, Mitchell, Newman, & Batshaw, 2001). This prospect is not without its difficulties, however (Durand, 2001).

One cause of concern is the reliability of gene therapy. This technology is not sufficiently advanced to produce the intended results consistently. Currently, any such intervention may cause unwanted mutations or other complications, which in turn could be fatal to the fetus. Gene therapy will probably not be practical for those disorders that involve numerous genes, but rather may be limited to single-gene disorders such as PKU.

Advances in biomedical technology will need support from psychological researchers to make sure that any needed treatments are carried out properly. For example, biological risk factors for several developmental disorders include malnutrition and exposure to toxins such as lead and alcohol. Although medical researchers can identify the role of these biological events in cognitive development, psychologists will need to support these efforts. Behavioral intervention for safety training (for example, involving lead-based paints in older homes), substance-use treatment and prevention, and behavioral medicine (for example, "wellness" efforts) are examples of crucial roles played by psychologists in helping to prevent certain forms of developmental disorders.

### Concept Check 14.3

In the following situations, label each level of intellectual disability as mild, moderate, severe, or profound. Also label the corresponding levels of necessary support: intermittent, limited, extensive, or pervasive.

1. Kevin received an IQ score of 20. He needs help with all his basic needs, including dressing, bathing, and eating. ____________, ____________
2. Adam received an IQ score of 45. He lives in a fully staffed group home and needs a great deal of help with many tasks. He is beginning to receive training for a job in the community. ____________, ____________
3. Jessica received an IQ score of 30. She lives in a fully staffed group home where she is trained in basic adaptive skills and communication. She is improving over time and can communicate by pointing or using her eye-gaze board. ____________, ____________
4. LeBron received an IQ score of 65. He lives at home, goes to school, and is preparing to work when he is through with school. ____________, ____________

### On the Spectrum

## Emerging Views of Developmental Disorders

The disorders described in this chapter represent a broad range of problems first evident in childhood (Durand, in press-a). Some of the disorders discussed may be considered part of a spectrum of disorders. For instance, some of the pervasive developmental disorders are being studied under the category of "autism spectrum disorders" and this change is being discussed for possible inclusion in *DSM-5.* Autistic disorder and Asperger's disorder are thought to be related in the spectrum, although research continues on the co-occurrence of childhood disintegrative disorder and pervasive developmental disorder not otherwise specified (PDD-NOS) (Swedo, Thorsen, & Pine, 2008).

Two other major disorders—conduct disorder (CD) and oppositional defiant disorder (ODD)—may be part of a spectrum of "disruptive behavior disorders," although this research is in a beginning stage (Shaffer, Leibenluft, Rohde, Sirovatka, & Regier, 2009). There is also considerable comorbidity among attention deficit disorder, CD, and ODD, although any conclusion about their being part of a spectrum of disorders is premature (Shaffer, Leibenluft, Rohde, Sirovatka, & Regier, in press). To move this research ahead in the coming years, researchers are examining the complex genetics of CD and ODD to see if there are meaningful ways to view these childhood problems and their apparent overlap (some children have some symptoms of both disorders).

# Summary

## Common Developmental Disorders

- Developmental psychopathology is the study of how disorders arise and change with time. These changes usually follow a pattern, with the child mastering one skill before acquiring the next. This aspect of development is important because it implies that any disruption in the acquisition of early skills will, by the very nature of the developmental process, also disrupt the development of later skills.
- The primary characteristics of people with attention deficit/hyperactivity disorder are a pattern of inattention (such as not paying attention to school- or work-related tasks), hyperactivity/impulsivity, or both. These deficits can significantly disrupt academic efforts and social relationships.
- *DSM-IV-TR* groups the learning disorders as reading disorder, mathematics disorder, and disorder of written expression. All are defined by performance that falls far short of expectations based on intelligence and school preparation.
- Verbal or communication disorders seem closely related to learning disorders. They include stuttering, a disturbance in speech fluency; expressive language disorder, limited speech in all situations but without the types of cognitive deficits that lead to language problems in people with intellectual disability or one of the pervasive developmental disorders; selective mutism, refusal to speak despite having the ability to do so; and tic disorders, which include involuntary motor movements such as head twitching and vocalizations such as grunts that occur suddenly, in rapid succession, and in idiosyncratic or stereotyped ways.

## Pervasive Developmental Disorders

- People with pervasive developmental disorders all experience trouble progressing in language, socialization, and cognition. The use of the word *pervasive* means these are not relatively minor problems (like learning disabilities) but are conditions that significantly affect how individuals live. Included in this group are autistic disorder, Rett's disorder, Asperger's disorder, and childhood disintegrative disorder.
- Autistic disorder, or autism, is a childhood disorder characterized by significant impairment in social interactions, gross and significant impairment in communication, and restricted patterns of behavior, interest, and activities. It probably does not have a single cause; instead, a number of biological conditions may contribute, and these, in combination with psychosocial influences, result in the unusual behaviors displayed by people with autism.
- Asperger's disorder is characterized by impairments in social relationships and restricted or unusual behaviors or activities, but people with Asperger's disorder do not have the language delays observed in people with autism.
- Rett's disorder, almost exclusively observed in females, is a progressive neurological disorder characterized by constant hand-wringing, intellectual disability, and impaired motor skills.
- Childhood disintegrative disorder involves severe regression in language, adaptive behavior, and motor skills after a period of normal development for 2 to 4 years.
- Pervasive developmental disorder not otherwise specified is a childhood disorder characterized by significant impairment in social interactions, gross and significant impairment in communication, and restricted patterns of behavior, interest, and activities. Children who have this disorder are similar to those with autism but may not meet the age criterion for autism or may not meet the criteria for some symptoms of autism.

## Intellectual Disability

- The definition of intellectual disability has three parts: significantly subaverage intellectual functioning, concurrent deficits or impairments in present adaptive functioning, and an onset before the age of 18.
- Down syndrome is a type of intellectual disability caused by the presence of an extra 21st chromosome. It is possible to detect the presence of Down syndrome in a fetus through a process known as amniocentesis.
- Two other types of intellectual disability are common: fragile X syndrome, which is caused by a chromosomal abnormality of the tip of the X chromosome, and cultural–familial intellectual disability, the presumed cause, possibly by a combination of psychosocial and biological factors, of up to 75% of intellectual disability.

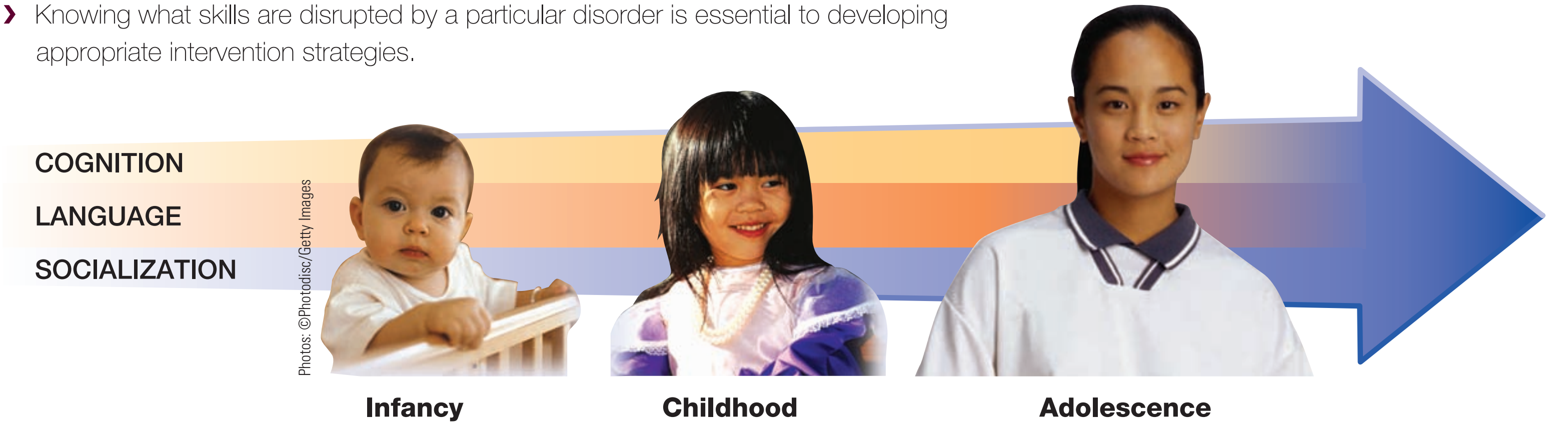
# Exploring Developmental Disorders

Disorders that appear early in life disrupt the normal course of development.

- Interrupting or preventing the development of one skill impedes mastery of the skill that is normally acquired next.
- Knowing what skills are disrupted by a particular disorder is essential to developing appropriate intervention strategies.



Photos: ©Photodisc/Getty Images

## TYPES OF DEVELOPMENTAL DISORDERS

| | | Description | Causes | Treatment |
|---|---|---|---|---|
| **Attention Deficit/ Hyperactivity Disorder (ADHD)** | <br>©Myrleen Ferguson Cate/PhotoEdit | • Inattentive, overactive, and impulsive behavior<br>• Disrupted schooling and relationships<br>• Symptoms may change with maturity, but problems persist.<br>• More prevalent in boys than girls | • Research suggests hereditary factor<br>• Abnormal neurology<br>• Possible link with maternal smoking<br>• Negative responses by others create low self-esteem. | • Biological (medication)<br>– improves compliance<br>– decreases negative behaviors<br>– effects not long term<br>• Psychological (behavioral)<br>– goal setting and reinforcement |
| **Learning Disorders** | <br>Used with permission of Laureate Learning Systems, Inc. | • Reading, math, and written expression fall behind IQ, age, and education.<br>• May also be accompanied by ADHD | • Theories assume genetic, neurobiological, and environmental factors. | • Education intervention<br>– basic processing<br>– cognitive and behavioral skills |

| | Types | Description | Treatment |
|---|---|---|---|
| **Communication Disorders**<br>Closely related to learning disorders, but comparatively benign. Early appearance, wide range of problems later in life.<br> <br>©Photodisc/Getty Images | **Stuttering** | Disturbance in speech fluency (repeating words, prolonging sounds, extended pauses) | • Psychological<br>• Pharmacological |
| | **Expressive Language Disorders** | Limited speech in all situations | • May be self-correcting |
| | **Selective Mutism** | Failure to speak in specific situations (e.g., school) | • Contingency management |
| | **Tic Disorders** | Involuntary motor movements (tics), such as physical twitches or vocalizations | • Psychological<br>• Pharmacological |

## PERVASIVE DEVELOPMENTAL DISORDERS

| | Description | Causes | Treatment |
|---|---|---|---|
| **Autistic Disorder** | • Severely impaired socialization and communication<br>• Restricted behavior, interests, and activities<br>– echolalia<br>– maintenance of sameness<br>– stereotyped, ritualistic behaviors<br>• Symptoms almost always develop before 36 months of age. | • Little conclusive data<br>• Numerous biological factors<br>– clear genetic component<br>– evidence of brain damage (cognitive deficits) combined with psychosocial influences | • Behavioral focus<br>– communication<br>– socialization<br>– living skills<br>• Inclusive schooling<br>• Temporary benefits from medication |
| **Asperger's Disorder** | Impaired socialization and restricted/unusual behaviors, but without language delays<br>• Few cognitive impairments (average IQ)<br>• May be mild autism, not separate disorder | | ©Photodisc/Getty Images |
| **Rett's Disorder** | Progressive neurological disorder after apparently normal early development<br>• Primarily affects girls<br>• Mental retardation<br>• Deteriorating motor skills<br>• Constant hand-wringing | | ©moodboard/Corbis |
| **Childhood Disintegrative Disorder** | Severe regression after 2–4 years normal development<br>• Affects language, adaptive behavior, and motor skills<br>• Evidence of neurological origin | | ©Paul Conklin/PhotoEdit |

## INTELLECTUAL DISABILITY

| | Description | Causes | Treatment |
|---|---|---|---|
| ©Photodisc/Getty Images | • Adaptive and intellectual functioning significantly below average<br>– language and communication impairments<br>• Wide range of impairment—from mild to profound—in daily activities (90% of affected individuals have mild impairments.) | • Hundreds of identified factors<br>– genetic<br>– prenatal<br>– perinatal<br>– postnatal<br>– environmental<br>• Nearly 75% of cases cannot be attributed to any known cause. | • No biological intervention<br>• Behavioral focus similar to that for autism<br>• Prevention<br>– genetic counseling<br>– biological screening<br>– maternal care |

## STUDENT LEARNING OUTCOMES*

| | |
|---|---|
| **Demonstrate knowledge and understanding representing appropriate breadth and depth in selected content areas of psychology:** | › Biological bases of behavior and mental processes, including physiology, sensation, perception, comparative, motivation, and emotion (APA SLO 1.2.a (3)) ***(see textbook pages 545–548)*** |
| **Use the concepts, language, and major theories of the discipline to account for psychological phenomena.** | › Describe behavior and mental processes empirically, including operational definitions (APA SLO 1.3.a) ***(see textbook pages 535–540)***<br>› Identify antecedents and consequences of behavior and mental processes (APA SLO 1.3.b) ***(see textbook pages 540–545)*** |
| **Identify appropriate applications of psychology in solving problems, such as:** | › Origin and treatment of abnormal behavior (APA SLO 4.2.b) ***(see textbook pages 545–553)*** |

---

* Portions of this chapter cover learning outcomes suggested by the American Psychological Association (2007) in their guidelines for the undergraduate psychology major. Chapter coverage of these outcomes is identified above by APA Goal and APA Suggested Learning Outcome (SLO).

## Perspectives on Cognitive Disorders

Research on the brain and its role in psychopathology has increased at a rapid pace, and we have described many of the latest advances throughout this book. All the disorders we have reviewed are in some way influenced by the brain. You have seen, for example, that relatively subtle changes in neurotransmitter systems can significantly affect mood, cognition, and behavior. Unfortunately, the brain is sometimes affected profoundly, and, when this happens, drastic changes occur. In earlier editions of this book, the tone of this chapter was quite dark given the lack of information on these cognitive disorders that impair all aspects of mental functioning. The typically poor prognosis of the people afflicted led to pessimistic conclusions. However, a great deal of new research is leading us to be more optimistic about the future. For example, we used to think that once neurons died there was no hope of any replacement, yet we now know brain cells can regenerate even in the aging brain (Stellos et al., 2010). In this chapter, we examine this exciting new work related to the brain disorders that affect cognitive processes such as learning, memory, and consciousness.

Whereas intellectual disability and other learning disorders are believed to be present from birth (see Chapter 14), most cognitive disorders develop much later in life. In this chapter, we review three classes of cognitive disorders: *delirium,* an often temporary condition displayed as confusion and disorientation; *dementia,* a progressive condition marked by gradual deterioration of a range of cognitive abilities; and *amnestic disorders,* dysfunctions of memory resulting from a medical condition or a drug or toxin.

The label "cognitive disorders" in the fourth edition, text revision, of the *Diagnostic and Statistical Manual (DSM-IV-TR)* reflects a shift in the way these disorders are viewed (Sweet, 2009). In previous editions of the *DSM,* they were labeled "organic mental disorders," along with mood, anxiety, personality, hallucinosis (an abnormal mental state involving hallucinations), and delusional disorders. The word *organic* indicated that brain damage or dysfunction was believed to be involved. Although brain dysfunction is still thought to be the primary cause of cognitive disorders, we now know that some dysfunction in the brain is involved in most disorders described in *DSM-IV-TR* (American Psychiatric Association Practice Guideline, 2000).

We have repeatedly emphasized the complex relationship between neurological and psychosocial influences in many psychological disorders. Few people would disagree, for example, that schizophrenia involves some damage to the brain. In one sense, then, most disorders are "organic." This fundamental shift in perspective immediately affected the categorizing of disorders. The term *organic mental disorders* covered so many as to make any distinction meaningless. Consequently, the traditional organic disorders—delirium, dementia, and amnestic disorders—were kept together, and the others—organic mood, anxiety, personality, hallucinosis, and delusional disorders—were categorized with disorders that shared their symptoms (such as anxiety and mood disorders).

Once the term *organic* was dropped, attention moved to developing a better label for delirium, dementia, and the amnestic disorders. The label "cognitive disorders" signifies that their predominant feature is the impairment of such cognitive abilities as memory, attention, perception, and thinking. Although disorders such as schizophrenia and depression also involve cognitive problems, cognitive issues are not believed to be primary characteristics. Problems still exist with this term, however, because although the cognitive disorders usually first appear in older adults, mental retardation and learning disorders (which are apparent early) also have cognitive impairment as a predominant characteristic. Currently, discussions are under way for *DSM-5* to keep the label "delirium" but to combine the other cognitive disorders (such as dementia and amnestic disorders) and call them "neurocognitive disorders"; their dimensional quality would be specified as either the "major" or "minor" subtype (American Psychiatric Association, 2010). In part, this may be the result of the overlap of the different types of dementia (e.g., Alzheimer's disorder) and amnestic disorder found in people such that one person may actually suffer from multiple types of neurocognitive problems (Sweet, 2009).

As with certain other disorders, it may be useful to clarify why cognitive disorders are discussed in a textbook on abnormal psychology. Because they so clearly have organic causes, you could argue that they are purely medical concerns. You will see, however, that the consequences of a cognitive disorder often include profound changes in a person's behavior and personality. Intense anxiety, depression, or both are common, especially among people with dementia. In addition, paranoia is often reported, as are extreme agitation and aggression. Families and friends are also profoundly affected by such changes. Imagine your emotional distress as a loved one is transformed into a different person, often one who no longer remembers who you are or your history together. The deterioration of cognitive ability, behavior, and personality and the effects on others are major concerns for mental health professionals.

## Delirium

The disorder known as **delirium** is characterized by impaired consciousness and cognition during the course of several hours or days. Delirium is one of the earliest-recognized mental disorders: Descriptions of people with these symptoms were written more than 2,400 years ago (Solai, 2009). Consider the case of Mr. J.

### MR. J. | *Sudden Distress*

Mr. J., an older gentleman, was brought to the hospital emergency room. He didn't know his own name, and at times he didn't seem to recognize his daughter, who was with him. Mr. J. appeared confused, disoriented, and a little agitated. He had difficulty speaking clearly and could not focus his attention to answer even the most basic questions. Mr. J.'s daughter reported that he had begun acting this way the night before, had been awake most of the time since then, was frightened, and seemed even more confused today. She told the nurse that this behavior was not normal for him and she was worried that he was becoming senile. She mentioned that his doctor had just changed his hypertension medication and wondered whether the new medication could be causing her father's distress. Mr. J. was ultimately diagnosed as having substance-induced delirium (a reaction to his new medication); once the medication was stopped, he improved significantly over the course of the next 2 days.

The preceding scenario is played out daily in most major metropolitan hospital emergency rooms.

### Clinical Description and Statistics

People with delirium appear confused, disoriented, and out of touch with their surroundings. They cannot focus and sustain their attention on even the simplest tasks. There are marked impairments in memory and language. Mr. J. had trouble speaking; he was not only confused but also couldn't remember basic facts, such as his own name. As you saw, the symptoms of delirium do not come on gradually but develop over hours or a few days, and they can vary over the course of a day.

Delirium is estimated to be present in as many as 30% of older adults who are admitted into acute care facilities such as emergency rooms (Fearing & Inouye, 2009). It is most prevalent among older adults, people undergoing medical procedures, cancer patients, and people with acquired immune deficiency syndrome (AIDS). Delirium subsides relatively quickly. Once thought to be only a temporary problem, more recent work indicates that the effects of delirium may be more lasting (Cole, Ciampi, Belzile, & Zhong, 2009). Some individuals continue to have problems on and off; some even lapse into a coma and may die. Concern by medical professionals is increasing—perhaps because of the increased number of adults living longer—leading some to recommend that delirium be included as one of the "vital signs" (along with heart beat, breathing rate, temperature, and blood pressure) that physicians routinely check when seeing older adults (Flaherty et al., 2007).

Many medical conditions that impair brain function have been linked to delirium, including intoxication by drugs and poisons; withdrawal from drugs such as alcohol and sedative, hypnotic, and anxiolytic drugs; infections; head injury; and various other types of brain trauma (Fearing & Inouye, 2009). *DSM-IV-TR* recognizes several causes of delirium among its subtypes. The criteria for delirium due to a general medical condition include a disturbance of consciousness (reduced awareness of the environment) and a change in cognitive abilities such as memory and language skills, occurring over a short period and brought about by a general medical condition. Other subtypes include the diagnosis received by Mr. J.—substance-induced delirium—as well as delirium due to multiple causes and delirium not otherwise specified. The rise in the use of drugs such as Ecstasy (methylenedioxymethamphetamine) is of particular concern because of such drugs' potential to produce delirium (Solai, 2009). The last two categories indicate the often complex nature of delirium.

That delirium can be brought on by the improper use of medication is a particular problem for older adults, because they tend to use prescription medications more than any other age group. The risk of problems among the elderly is increased further because they tend to eliminate drugs from their systems less efficiently than younger individuals. It is not surprising, then, that adverse drug reactions resulting in hospitalization are almost 6 times higher among elderly people than in other age groups (Olivier et al., 2009). And it is believed that delirium is responsible for many of the falls that cause debilitating hip fractures in the elderly (Stenvall et al., 2006). Although there has been some improvement in the use of medication among older adults with physicians using more care with drug dosages and the use of multiple drugs, improper use continues to produce serious side effects, including symptoms of delirium (Olivier et al., 2009). Because possible combinations of illnesses and medications are so numerous, determining the cause of delirium is extremely difficult (Solai, 2009).

Delirium may be experienced by children who have high fevers or who are taking certain medications and is often mistaken for noncompliance (Smeets et al., 2010). It often occurs during the course of dementia; as many as 50% of people with dementia suffer at least one episode of delirium (Kwok, Lee, Lam, & Woo, 2008). Because many of the primary medical conditions can be treated, delirium is often reversed within a relatively short time. Yet, in about a quarter of cases, delirium can be a sign of the end of life (Wise, Hilty, & Cerda, 2001).

Factors other than medical conditions can trigger delirium. Age itself is an important factor; older adults are more susceptible

**DSM-IV-TR**

### **Table 15.1** Diagnostic Criteria for Delirium Due to . . . [Indicate the General Medical Condition]

**A.** Disturbance of consciousness (i.e., reduced clarity of awareness of the environment) with reduced ability to focus, sustain, or shift attention.

**B.** A change in cognition (such as memory deficit, disorientation, language disturbance) or the development of a perceptual disturbance that is not better accounted for by a preexisting, established, or evolving dementia.

**C.** The disturbance develops over a short period of time (usually hours to days) and tends to fluctuate during the course of the day.

**D.** There is evidence from the history, physical examination, or laboratory findings that the disturbance is caused by the direct physiological consequences of a general medical condition.

to developing delirium as a result of mild infections or medication changes (Fearing & Inouye, 2009). Sleep deprivation, immobility, and excessive stress can also cause delirium (Solai, 2009).

## Treatment

Delirium brought on by withdrawal from alcohol or other drugs is usually treated with haloperidol or other antipsychotic medications, which help calm the individual. Infections, brain injury, and tumors are given the necessary and appropriate medical intervention, which often then resolves the accompanying delirium. The antipsychotic drug haloperidol is also prescribed for individuals in acute delirium when the cause is unknown (Fearing & Inouye, 2009).

The recommended first line of treatment for a person experiencing delirium is psychosocial intervention. The goal of nonmedical treatment is to reassure the individual to help him or her deal with the agitation, anxiety, and hallucinations of delirium. A person in the hospital may be comforted by familiar personal belongings such as family photographs (Fearing & Inouye, 2009). Also, a patient who is included in all treatment decisions retains a sense of control (Katz, 1993). This type of psychosocial treatment can help the person manage during this disruptive period until the medical causes are identified and addressed. Some evidence suggests that this type of support can also delay institutionalization for elderly patients (Rahkonen et al., 2001).

## Prevention

Preventive efforts may be most successful in assisting people who are susceptible to delirium. Proper medical care for illnesses and therapeutic drug monitoring can play significant roles in preventing delirium (Fearing & Inouye, 2009). For example, the increased number of older adults involved in managed care and patient counseling on drug use appear to have led to more appropriate use of prescription drugs among the elderly (U.S. General Accounting Office, 1995).

### Concept Check 15.1

Match the terms with the following descriptions of delirium: (a) memory, (b) cause, (c) counseling, (d) confused, (e) elderly, and (f) trauma.

1. Managed care and patient ____________ have been successful in preventing delirium in older adults.
2. Treatment of delirium depends on the ____________ of the episode and can include medications, psychosocial intervention, or both.
3. Delirium severely affects people's ____________, making tasks such as recalling one's own name difficult.
4. The ____________ population is at the greatest risk of experiencing delirium resulting from improper use of medications.
5. Various types of brain ____________, such as head injury or infection, have been linked to delirium.
6. People who suffer from delirium appear to be ____________ or out of touch with their surroundings.

## Dementia

Few things are more frightening than the possibility that you will one day not recognize those you love, that you will not be able to perform the most basic of tasks, and, worse yet, that you will be acutely aware of this failure of your mind. When family members show these signs, initially adult children often deny any difficulty, coming up with excuses ("I forget things, too") for their parents' failing abilities. **Dementia** is the cognitive disorder that makes these fears real: a gradual deterioration of brain functioning that affects judgment, memory, language, and other advanced cognitive processes. Dementia is caused by several medical conditions and by the abuse of drugs or alcohol that cause negative changes in cognitive functioning. Some of these conditions—for instance, infection or depression—can cause dementia, although it is often reversible through treatment of the primary condition. Some forms of the disorder, such as Alzheimer's disease, are at present irreversible. Although delirium and dementia can occur together, dementia has a gradual progression as opposed to delirium's acute onset; people with dementia are not disoriented or confused in the early stages, unlike people with delirium. Like delirium, however, dementia has many causes, including a variety of traumas to the brain such as stroke (which destroys blood vessels), the infectious diseases of syphilis and HIV, severe head injury, the introduction of certain toxic or poisonous substances, and diseases such as Parkinson's, Huntington's, and, the most common cause of dementia, Alzheimer's. Consider the personal account by Diana, a woman who poignantly writes of her experiences with this disorder (McGowin, 1993).

### **DIANA** | *Humiliation and Fear*

At the age of 45, Diana Friel McGowin was a successful legal assistant, wife, and mother, but she was beginning to experience "lapses." She writes about developing these problems just before a party she was planning for her family.

> Nervously, I checked off the table appointments on a list retrieved from my jumpsuit pocket. Such a list had never been necessary before, but lately I noticed frequent little episodes of confusion and memory lapses.
>
> I had decided to "cheat" on this family buffet and have the meal prepared on a carry-out basis. Cooking was also becoming increasingly difficult, due to what my children and my husband Jack teasingly referred to as my "absentmindedness." (pp. 1–2)

In addition to memory difficulties, other problems began at this time, including brief dizzy spells. Diana wrote of her family's growing awareness of the additional symptoms.

> Shaun walked past me on his way to the kitchen, and paused. "Mom, what's up? You look ragged," he commented sleepily. "Late night last night, plenty of excitement, and then up early to get your father off to work," I answered. Shaun laughed disconcertingly. I glanced up at him ruefully. "What is so funny?" I demanded. "You, Mom! You are talking as though you are drunk or something! You must really be tired!" (pp. 4–5)

In the early stages of her dementia, Diana tended to explain these changes in herself as temporary, with such causes as tension at work. However, the extent of her dysfunction continued to increase, and she had more frightening experiences. In one episode, she describes an attempt to drive home from a brief errand.

> Suddenly, I was aware of car horns blowing. Glancing around, nothing was familiar. I was stopped at an intersection and the traffic light was green. Cars honked impatiently, so I pulled straight ahead, trying to get my bearings. I could not read the street sign, but there was another sign ahead; perhaps it would shed some light on my location. A few yards ahead, there was a park ranger building. Trembling, I wiped my eyes, and breathing deeply, tried to calm myself. Finally, feeling ready to speak, I started the car again and approached the ranger station. The guard smiled and inquired how he could assist me. "I appear to be lost," I began, making a great effort to keep my voice level, despite my emotional state. "Where do you need to go?" the guard asked politely. A cold chill enveloped me as I realized I could not remember the name of my street. Tears began to flow down my cheeks. I did not know where I wanted to go. (pp. 7–8)

Diana's difficulties continued. She sometimes forgot the names of her children, and once she astounded her nephew when she didn't recognize him. If she left home, she almost invariably got lost. She learned to introduce herself as a tourist from out of town, because people would give her better directions. She felt as if there "was less of me every day than there was the day before" (p. 33).

During initial medical examinations, Diana didn't recall this type of problem in her family history. However, a look through some of her late mother's belongings revealed that she was not the first to experience symptoms of dementia.

> Then I noticed the maps. After mother's death I had found mysterious hand drawn maps and bits of directions scribbled on note papers all over her home. They were in her purses, in bureau drawers, in the desks, seemingly everywhere. Too distraught at the time to figure out their purpose, I simply packed them all away with other articles in the box. Now I smoothed out each map and scrawled note, and placed them side by side. They covered the bedroom floor. There were maps to every place my mother went about town, even to my home and my brother's home. As I deciphered each note and map, I began recollecting my mother's other eccentric habits. She would not drive out of her neighborhood. She would not drive at night. She was teased by both myself and my brother about "memory goofs" and would become irate with both of her children over their loving teasing.
>
> Then with a chill, I recalled one day when I approached my mother to tell her something, and she did not recognize me. (p. 52)

After several evaluations, which included magnetic resonance imaging (MRI) showing some damage in several parts of her brain, Diana's neurologist concluded that she had dementia. The cause could be a stroke she had had years before that damaged several small areas of her brain by breaking or blocking several blood vessels. The dementia could also indicate Alzheimer's disease. People at the same stage of decline as Diana will continue to deteriorate and eventually may die from complications of their disorder.

## Clinical Description and Statistics

Depending on the individual and the cause of the disorder, the gradual progression of dementia may have somewhat different symptoms, although all aspects of cognitive functioning are eventually affected. In the initial stages, memory impairment is typically seen as an inability to register ongoing events. In other words, a person can remember how to talk and may remember events from many years ago but will have trouble remembering what happened in the past hour. For example, Diana still knew how to use the stove but couldn't remember whether she had turned it on or off.

Diana couldn't find her way home because visuospatial skills are impaired among people with dementia. **Agnosia**, the inability to recognize and name objects, is one of the most familiar symptoms. **Facial agnosia**, the inability to recognize even familiar faces, can be extremely distressing to family members. Diana failed to recognize not only her nephew but also coworkers whom she had seen daily for years. A general deterioration of intellectual function results from impairment in memory, planning, and abstract reasoning.

Perhaps partly because people suffering from dementia are aware that they are deteriorating mentally, emotional changes often occur as well. Common side effects are delusions (irrational beliefs), depression, agitation, aggression, and apathy (Richards & Sweet, 2009). Again, it is difficult to establish the cause-and-effect relationship. It is not known how much behavioral change is caused by progressive brain deterioration directly and how much is a result of the frustration and discouragement that inevitably accompany the loss of function and the isolation of "losing" loved ones. Cognitive functioning continues to deteriorate until the person requires almost total support to carry out day-to-day activities. Ultimately, death occurs as the result of inactivity, combined with the onset of other illnesses, such as pneumonia.

Globally, it is estimated that one new case of dementia is identified every 7 seconds (Ferri et al., 2005). Dementia can occur at almost any age, although this disorder is more frequent in older adults. Current estimates in the United States suggest a prevalence of a little more than 5% in people older than 65; this rate increases to 20%–40% in those older than 85 (Richards & Sweet, 2009). Estimates of the increasing number of people with just one form of dementia—dementia of the Alzheimer's type—are alarming. Table 15.1 illustrates how the prevalence of dementia of the Alzheimer's type is projected to dramatically increase in older adults, partly as a result of the increase of baby boomers who will become senior citizens (Hebert, Scherr, Bienias, Bennett, & Evans, 2003). Among the eldest of adults, research on centenarians (people 100 years and older) indicates that up to 100% showed signs of dementia (Imhof et al., 2007). Dementia of the Alzheimer's type rarely occurs in people under 45 years of age.

**TABLE 15.1** Estimates of Prevalence of Alzheimer's Disease in the United States Through 2050 (in millions)

| Year | Age 65–74 | Age 75–84 | Age 85 and older |
|---|---|---|---|
| 2000 | 0.3 | 2.4 | 1.8 |
| 2010 | 0.3 | 2.4 | 2.4 |
| 2020 | 0.3 | 2.6 | 2.8 |
| 2030 | 0.5 | 3.8 | 3.5 |
| 2040 | 0.4 | 5.0 | 5.6 |
| 2050 | 0.4 | 4.8 | 8.0 |

*Source:* Adapted from Hebert, L. E., Scherr, P. A., Bienias, J. L., Bennett, D. A., & Evans, D. A. (2003). Alzheimer disease in the U.S. population: Prevalence estimates using the 2000 Census. *Archives of Neurology, 60,* 1119–1122.

A problem with confirming prevalence figures for dementia is that survival rates alter the outcomes. Because adults are generally living longer and therefore more are at greater risk of developing dementia, it is not surprising that dementia is more prevalent. Incidence studies, which count the number of new cases in a year, may thus be the most reliable method for assessing the frequency of dementia, especially among the elderly. Research shows that the rate for new cases doubles with every 5 years of age after age 75. Many studies find greater increases of dementia

©Francisco Cruz/SuperStock

▲ People with facial agnosia, a common symptom of dementia, are unable to recognize faces, even of their closest friends and relatives.

among women (Richards & Sweet, 2009), although this may be because of the tendency of women to live longer. Dementia of the Alzheimer's type may, as we discuss later, be more prevalent among women. Together, results suggest that dementia is a relatively common disorder among older adults and the chances of developing it increase rapidly after the age of 75.

In addition to the human costs of dementia, the financial costs are staggering. Estimates of the costs of caring for people with dementia of the Alzheimer's type are often quoted to be about $100 billion per year in the United States. One estimate indicates that the total worldwide societal cost of dementia is more than $315 billion (Wimo, Winblad, & Jonsson, 2007). However, these numbers do not factor in the costs to businesses for health care in the form of insurance and for those who care for these individuals—estimated to be more than $140 billion in the United States alone (Weiner et al., 2010). Many times, family members care for an afflicted person around the clock, which is an inestimable personal and financial commitment (Richards & Sweet, 2009).

The statistics on prevalence and incidence cover dementias that arise from a variety of causes. *DSM-IV-TR* groups are based on presumed cause, but determining the cause of dementia is an inexact process. Sometimes, as with dementia of the Alzheimer's type, clinicians rely on ruling out alternative explanations—identifying all the things that are not the cause—instead of determining the precise origin.

Five classes of dementia based on etiology have been identified: (1) dementia of the Alzheimer's type; (2) vascular dementia; (3) dementia due to other general medical conditions; (4) substance-induced persisting dementia; (5) dementia due to multiple etiologies; and (6) dementia not otherwise specified, when cause cannot be determined. We emphasize dementia of the Alzheimer's type because of its prevalence (almost half of those with dementia exhibit this type) and the relatively large amount of research conducted on its etiology and treatment.

## Dementia of the Alzheimer's Type

The German psychiatrist Alois Alzheimer first described the disorder that bears his name in 1907. He wrote of a 51-year-old woman who had a "strange disease of the cerebral cortex" that manifested as a progressive memory impairment and other behavioral and cognitive problems, including suspiciousness (Richards & Sweet, 2009). He called the disorder an "atypical form of senile dementia"; thereafter, it was referred to as **Alzheimer's disease**.

### Description and Statistics

The *DSM-IV-TR* diagnostic criteria for **dementia of the Alzheimer's type** include multiple cognitive deficits that develop gradually and steadily. Predominant are impairment of memory, orientation, judgment, and reasoning. The inability to integrate new information results in failure to learn new associations. Individuals with Alzheimer's disease forget important events and lose objects. Their interest in nonroutine activities narrows. They tend to lose interest in others and, as a result, become more socially isolated. As the disorder progresses, they can become agitated, confused, depressed, anxious, or even combative. Many of these difficulties become more pronounced late in the day—in a phenomenon referred to as "sundowner syndrome"—perhaps as a result of fatigue or a disturbance in the brain's biological clock (Lemay & Landreville, 2010).

People with dementia of the Alzheimer's type also display one or more other cognitive disturbances, including aphasia (difficulty with language), apraxia (impaired motor functioning), agnosia (failure to recognize objects), or difficulty with activities such as planning, organizing, sequencing, or abstracting information. These cognitive impairments have a serious negative impact on social and occupational functioning, and they represent a significant decline from previous abilities.

Research using brain scans is being conducted on people with mild cognitive impairment to see whether changes in brain structure early in the development of Alzheimer's disease can be detected, which can lead to early diagnosis. In the past, a definitive diagnosis of Alzheimer's disease could be made only after an autopsy determined that certain characteristic types of damage were present in the brain. However, there is now growing evidence that the use of sophisticated brain scans along with new chemical tracers may soon be able to help clinicians identify the presence of Alzheimer's disease before the significant declines in cognitive abilities (through a project called the Alzheimer's Disease Neuroimaging Initiative [ADNI]) or death (Weiner et al., 2010). Currently, to make a diagnosis without direct examination of the brain, a simplified version of a mental status exam is used to assess language and memory problems (see Table 15.2).

In an interesting, somewhat controversial study—referred to as the "Nun Study"—the writings of a group of Catholic nuns collected over several decades appeared to indicate early in life which women were most likely to develop Alzheimer's disease later (Snowdon et al., 1996). Researchers observed that samples from the nuns' journals over the years differed in the number of ideas each contained, which the scientists called "idea density." In other words, some sisters described events in their lives simply: "I was born in Eau Claire, Wis, on May 24, 1913 and was baptized in St. James Church." Others were more elaborate in their prose: "The happiest day of my life so far was my First Communion Day which was in June nineteen hundred and twenty when I was but eight years of age, and four years later in the same month I was confirmed by Bishop D. D. McGavich" (Snowdon et al., 1996, pg., 530). When findings of autopsies on 14 of the nuns were correlated with idea density, the simple writing (low idea density) occurred among all 5 nuns with Alzheimer's disease (Snowdon et al., 1996). This is an elegant research study, because the daily lives of the nuns were similar, which ruled out many other possible causes. However, there is some concern about overgeneralizing from this one study and we must be cautious about depending too much on these observations, because only a small number of people were examined. It is not yet clear that dementia of the Alzheimer's type has such early signs, but research continues in the hope of early detection so that early intervention can be developed (Tyas et al., 2007).

Cognitive deterioration of the Alzheimer's type is slow during the early and later stages but more rapid during the middle stages (Richards & Sweet, 2009). The average survival time is estimated to be about 8 years, although many individuals live dependently for more than 10 years. In some forms, the disease can occur relatively early, during the 40s or 50s (sometimes referred to as *presenile dementia*), but it usually appears during the 60s or 70s.

**TABLE 15.2** Testing for Dementia of the Alzheimer's Type

| Type* | Maximum Score† | Question |
|---|---|---|
| Orientation | 5<br>5 | Ask the patient, "What is the (year) (season) (date) (day) (month)?"<br>Ask the patient, "Where are we—(state) (country) (town) (hospital) (floor)?" |
| Registration | 3 | Name three objects, using 1 second to say each. Then ask the patient all three after you have said them. (Give one point for each correct answer.) Then repeat them until the patient learns all three. (Count and record the number of trials.) |
| Attention and Calculation | 5 | Count backward from given number (like 100) by subtracting 7s. (Give one point for each correct answer; stop after five answers.) Alternatively, spell "world" backward. |
| Recall | 3 | Have the patient name the three objects learned previously. (Give one point for each correct answer.) |
| Language | 9 | Have the patient name a pencil and a watch. (1 point)<br>Have the patient repeat the following: "No ifs, ands, or buts." (1 point)<br>Have the patient follow a three-stage command: "Take a piece of paper in your right hand, fold it in half, and put it on the floor." (3 points)<br>Have the patient read and obey the following: "Close your eyes." (1 point)<br>Have the patient write a sentence. (1 point)<br>Have the patient copy a design. (1 point) |

*Note:* One part of the diagnosis of the dementia of Alzheimer's disease uses a relatively simple test of the patient's mental state and abilities, like this one, called the Mini Mental State Inpatient Consultation Form. A low score on such a test does not necessarily indicate a medical diagnosis of dementia.

*The examination also includes an assessment of the patient's level of consciousness: alert, drowsy, stupor, or coma.

†Total maximum score is 30.

Adapted from the Mini Mental State Inpatient Consultation Form, Folstein, Folstein, & McHugh.

Approximately 50% of the cases of dementia are found to be the result of Alzheimer's disease, which is believed to afflict more than 5 million Americans and millions more worldwide (Alzheimer's Association, 2010).

Some early research on prevalence suggested that Alzheimer's disease may occur more often in people who are poorly educated (Fratiglioni et al., 1991; Korczyn, Kahana, & Galper, 1991). Greater impairment among uneducated people might indicate a much earlier onset, suggesting that Alzheimer's disease causes intellectual dysfunction that in turn hampers educational efforts. Or there could be something about intellectual achievement that prevents or delays the onset of symptoms of the disorder. Later research seems to confirm the latter explanation. It appears that educational level may predict a delay in the observation of symptoms (Perneczky et al., 2009). Unfortunately, people who attain a higher level of education also decline more rapidly once the symptoms start to occur (Scarmeas, Albert, Manly, & Stern, 2006), suggesting that education does not prevent Alzheimer's disease but just provides a buffer period of better functioning. Educational attainment may somehow create a mental "reserve," a learned set of skills that help someone cope longer with the cognitive deterioration that marks the beginning of dementia. Like Diana's mother, who made copious notes and maps to help her function despite her cognitive deterioration, some people may adapt more successfully than others and thus escape detection longer. Brain deterioration may thus be comparable for both groups, but better-educated individuals may be able to function successfully on a day-to-day basis for a longer period. This tentative hypothesis may prove useful in designing treatment strategies, especially during the early stages of the disorder.

A biological version of this theory—the cognitive reserve hypothesis—suggests that the more synapses a person develops throughout life, the more neuronal death must take place before the signs of dementia are obvious (Stern, 2009). Mental activity that occurs with education presumably builds up this reserve of synapses and serves as an initial protective factor in the development of the disorder. It is likely that both skill development and the changes in the brain with education may contribute to how quickly the disorder progresses.

Research suggests that Alzheimer's disease may be more prevalent among women (Craig & Murphy, 2009), even when women's higher survival rate is factored into the statistics. In other words, because women live longer than men on average, they are more likely to experience Alzheimer's and other diseases,

### DSM-IV-TR **Table 15.2** Diagnostic Criteria for Dementia of the Alzheimer's Type

- **A.** The development of multiple cognitive deficits manifested by both
  - **1.** Memory impairment (impaired ability to learn new information or to recall previously learned information)
  - **2.** One (or more) of the following cognitive disturbances:
    - **a.** Aphasia (language disturbance)
    - **b.** Apraxia (impaired ability to carry out motor activities despite intact motor function)
    - **c.** Agnosia (failure to recognize or identify objects despite intact sensory function)
    - **d.** Disturbance in executive functioning (i.e., planning, organizing, sequencing, abstracting)
- **B.** The cognitive deficits in criteria A1 and A2 each cause significant impairment in social or occupational functioning and represent a significant decline from a previous level of functioning.
- **C.** The course is characterized by gradual onset and continuing cognitive decline.
- **D.** The cognitive deficits in criteria A1 and A2 are not due to any of the following:
  - **1.** Other central nervous system conditions that cause progressive deficits in memory and cognition (e.g., cerebrovascular disease, Parkinson's disease, Huntington's disease, subdural hematoma, normal-pressure hydrocephalus, brain tumor)
  - **2.** Systemic conditions that are known to cause dementia (e.g., hypothyroidism, vitamin $B_{12}$ or folic acid deficiency, niacin deficiency, hypercalcemia, neurosyphilis, HIV infection)
  - **3.** Substance-induced conditions
- **E.** The deficits do not occur exclusively during the course of a delirium.
- **F.** The disturbance is not better accounted for by another Axis I disorder (e.g., major depressive disorder, schizophrenia).

but longevity alone does not account for the higher prevalence of the disorder among women. A tentative explanation involves the hormone estrogen. Women lose estrogen as they grow older, so perhaps estrogen is protective against the disease. A large and important study—the Women's Health Initiative Memory Study—looked at hormone use among women and its effect on Alzheimer's disease (Shumaker et al., 2004). In its initial findings, the study followed women over age 65 using a type of combined estrogen plus progestin known as Prempro and, contrary to the belief that giving women estrogen would decrease their chance of developing dementia, they observed an *increased* risk for Alzheimer's disease (Coker et al., 2010). More research is ongoing into the individual effects of these two types of hormones on dementia.

Finally, there appear to be questions about the prevalence of Alzheimer's disease according to racial identity. Early research seemed to suggest that certain populations (such as those with Japanese, Nigerian, certain Native American, and Amish backgrounds) were less likely to be affected (for example, see Pericak-Vance et al., 1996; Rosenberg et al., 1996). However, more recent work indicates that some of these differences may have been the result of differences in who seeks assistance (which is seen as unacceptable in some cultural groups), as well as differences in education (which we saw may delay the onset of obvious symptoms) (Wilson et al., 2010). Alzheimer's disease is found in roughly the same numbers across all ethnic groups, with one study finding a slightly lower rate among American Indians (Weiner, Hynan, Beekly, Koepsell, & Kukull, 2007). As you will see, findings like these help bring us closer to understanding the causes of this devastating disease.

## Vascular Dementia

Each year, 500,000 people die from strokes (any diseases or traumas to the brain that result in restriction or cessation of blood flow). Although stroke is the third-leading cause of death in the United States, many people survive, but one potential long-term consequence can be severely debilitating. **Vascular dementia** is a progressive brain disorder that is a common cause of dementia (Richards & Sweet, 2009).

### DSM-IV-TR **Table 15.3** Diagnostic Criteria for Vascular Dementia

- **A.** The development of multiple cognitive deficits manifested by both
  - **1.** Memory impairment (impaired ability to learn new information or to recall previously learned information)
  - **2.** One (or more) of the following cognitive disturbances:
    - **a.** Aphasia (language disturbance)
    - **b.** Apraxia (impaired ability to carry out motor activities despite intact motor function)
    - **c.** Agnosia (failure to recognize or identify objects despite intact sensory function)
    - **d.** Disturbance in executive functioning (i.e., planning, organizing, sequencing, abstracting)
- **B.** The cognitive deficits in criteria A1 and A2 each cause significant impairment in social or occupational functioning and represent a significant decline from a previous level of functioning.
- **C.** Focal neurological signs and symptoms (e.g., exaggeration of deep tendon reflexes, extensor plantar response, pseudobulbar palsy, gait abnormalities, weakness of an extremity) or laboratory evidence indicative of cerebrovascular disease (e.g., multiple infarctions involving cortex and underlying white matter) that are judged to be etiologically related to the disturbance.
- **D.** The deficits do not occur exclusively during the course of a delirium.

  With delirium: If delirium is superimposed on the dementia.

  With delusions: If delusions are the predominant feature.

  With depressed mood: If depressed mood (including presentations that meet full symptom criteria for a major depressive episode) is the predominant feature. A separate diagnosis of mood disorder due to a general medical condition is not given.

  Uncomplicated: If none of the above predominates in the current clinical presentation.

### Description and Statistics

The word *vascular* refers to blood vessels. When the blood vessels in the brain are blocked or damaged and no longer carry oxygen and other nutrients to certain areas of brain tissue, damage results. MRI scans of Diana's brain showed a number of damaged areas, or multiple infarctions, left by a stroke several years earlier; this was one probable cause of her dementia. Because multiple sites in the brain can be damaged, the profile of degeneration—the particular skills that are impaired—differs from person to person. *DSM-IV-TR* lists as criteria for vascular dementia the memory and other cognitive disturbances that are identical to those for dementia of the Alzheimer's type. However, certain neurological signs of brain tissue damage, such as abnormalities in walking and weakness in the limbs, are observed in many people with vascular dementia but not in people in the early stages of dementia of the Alzheimer's type. However, this distinction between vascular dementia and dementia of the Alzheimer's type is controversial and the two types may overlap more than previously thought (Lyketos, 2009).

In comparison with research on dementia of the Alzheimer's type, there are fewer studies on vascular dementia, perhaps because of its lower incidence rates. The prevalence of vascular dementia is approximately 1.5% in people 70 to 75 years of age and increases to 15% for those over the age of 80 (Neugroschi, Kolevzon, Samuels, & Marin, 2005). The risk for men is slightly higher than among women, in contrast with the higher risk among women for Alzheimer's type dementia, and this has been reported in many developed and developing countries (Kalaria et al., 2008). The relatively high rate of cardiovascular disease among men in general may account for their increased risk of vascular dementia. The onset of vascular dementia is typically more sudden than the onset for the Alzheimer's type, probably because the disorder is the result of stroke, which inflicts brain damage immediately. The outcome, however, is similar for people with both types: Ultimately, they will require formal nursing care until they succumb to an infectious disease such as pneumonia, to which they are susceptible because of weakening of the immune system.

## Dementia Due to Other General Medical Conditions

In addition to Alzheimer's disease and vascular damage, a number of other neurological and biochemical processes can lead to dementia. As you will see next, a variety of diseases can cause the loss of previous levels of cognitive abilities.

### Descriptions and Statistics

*DSM-IV-TR* lists several other types of dementia with specific causes, including dementia due to HIV disease, dementia due to head trauma, dementia due to Parkinson's disease, dementia due to Huntington's disease, dementia due to Pick's disease, and dementia due to Creutzfeldt-Jakob disease. Each of these is discussed here. Other medical conditions that can lead to dementia include normal pressure hydrocephalus (excessive water in the cranium, resulting from brain shrinkage), hypothyroidism (an underactive thyroid gland), brain tumor, and vitamin $B_{12}$ deficiency. There is increasing recognition of dementia in former boxers or other athletes who receive repeated blows to the head. In the past this type of dementia was referred to as *dementia pugilistica* (which suggested that it was restricted to boxers or pugilists) but it is currently referred to as *chronic traumatic encephalopathy (CTE)*. CTE is caused by repetitive **head trauma** that can provoke distinctive neurodegeneration (Gavett, Stern, Cantu, Nowinski, & McKee, 2010). In their effect on cognitive ability, all of these disorders are comparable to the other forms of dementia we have discussed so far.

**DSM-IV-TR**

### Table 15.4 Diagnostic Criteria for Dementia Due to Other General Medical Conditions

**A.** The development of multiple cognitive deficits manifested by both
  **1.** Memory impairment (impaired ability to learn new information or to recall previously learned information)
  **2.** One (or more) of the following cognitive disturbances:
    **a.** Aphasia (language disturbance)
    **b.** Apraxia (impaired ability to carry out motor activities despite intact motor function)
    **c.** Agnosia (failure to recognize or identify objects despite intact sensory function)
    **d.** Disturbance in executive functioning (i.e., planning, organizing, sequencing, abstracting)
**B.** The cognitive deficits in criteria A1 and A2 each cause significant impairment in social or occupational functioning and represent a significant decline from a previous level of functioning.
**C.** There is evidence from the history, physical examination, or laboratory findings that the disturbance is the direct physiological consequence of one of the general medical conditions listed below.
**D.** The deficits do not occur exclusively during the course of a delirium.

Dementia due to HIV disease
Dementia due to head trauma
Dementia due to Parkinson's disease
Dementia due to Huntington's disease
Dementia due to Pick's disease
Dementia due to Creutzfeldt-Jakob disease
Dementia due to (indicate the general medical condition not listed above)
  For example, normal-pressure hydrocephalus, hypothyroidism, brain tumor, vitamin $B_{12}$ deficiency, intracranial radiation

The **human immunodeficiency virus type 1 (HIV-1)**, which causes AIDS, can also cause dementia (Rappaport & Berger, 2010). This impairment seems to be independent of the other infections that accompany HIV; in other words, the HIV infection itself seems to be responsible for the neurological impairment. The early symptoms of dementia resulting from HIV are cognitive slowness, impaired attention, and forgetfulness. Affected individuals also tend to be clumsy, to show repetitive movements such as tremors and leg weakness, and to become apathetic and socially withdrawn.

People with HIV seem particularly susceptible to impaired thinking in the later stages of HIV infection, although significant

▲ Repeated blows to the head, which are common among boxers, football players, and other athletes, can increase the risk of developing dementia.

declines in cognitive abilities may occur earlier. Cognitive impairments were highly common among those infected with AIDS, but with the introduction of new medications (highly active antiretroviral therapies, or HAARTs) less than 10% of patients now experience dementia (Neugroschi et al., 2005). HIV-1 accounts for a relatively small percentage of people with dementia compared to Alzheimer's disease and vascular causes, but its presence can complicate an already-devastating set of medical conditions.

Like dementia from Parkinson's disease, Huntington's disease, and several other causes, dementia resulting from HIV is sometimes referred to as *subcortical dementia,* because it affects primarily the inner areas of the brain, below the outer layer called the cortex (Bourgeois, Seaman, & Servis, 2003). The distinction between cortical (including dementia of the Alzheimer's type) and subcortical dementia is important because of the different expressions of dementia in these two categories (see Table 15.3). **Aphasia**, which involves impaired language skills, occurs among people with dementia of the Alzheimer's type but not among people with subcortical dementia. In contrast, people with subcortical dementia are more likely to experience severe depression and anxiety than those with dementia of the Alzheimer's type. In general, motor skills including speed and coordination are impaired early on among those with subcortical dementia. The differing patterns of impairment can be attributed to the different areas of the brain affected by the disorders causing the dementia.

**Parkinson's disease** is a degenerative brain disorder that affects about 1 in every 1,000 people worldwide (Marsh & Margolis, 2009). Movie and television star Michael J. Fox and former Attorney General Janet Reno both suffer from this progressive disorder. Motor problems are characteristic among people with Parkinson's disease, who tend to have stooped posture, slow body movements (called *bradykinesia*), tremors, and jerkiness in walking. The voice is also affected; afflicted individuals speak in a soft monotone. The changes in motor movements are the result of damage to dopamine pathways. Because dopamine is involved in complex movement, a reduction in this neurotransmitter makes affected individuals increasingly unable to control their muscle movements, which leads to tremors and muscle weakness. The course of the disease varies widely, with some individuals functioning well with treatment.

It is estimated that about 75% of people who survive more than 10 years with Parkinson's disease develop dementia; conservative estimates place the rate at 4 to 6 times that found in the general population (Aarsland & Kurz, 2010). The pattern of impairments for these individuals fits the general pattern of subcortical dementia (see Table 15.3).

**Huntington's disease** is a genetic disorder that initially affects motor movements, typically in the form of *chorea,* involuntary limb movements (Marsh & Margolis, 2009). People with Huntington's disease can live for 20 years after the first signs of the disease appear, although skilled nursing care is often required during the last stages. Just as with Parkinson's disease, only a portion of people with Huntington's disease go on to display dementia—somewhere between 20% and 80%—although some researchers believe that all patients with Huntington's disease would eventually display dementia if they lived long enough (Marsh & Margolis, 2009). Dementia resulting from Huntington's disease also follows the subcortical pattern.

▲ The AIDS virus may cause dementia in the later stages.

The search for the gene responsible for Huntington's disease is like a detective story. For some time, researchers have known that the disease is inherited as an autosomal dominant disorder, meaning that approximately 50% of the offspring of an adult with Huntington's disease will develop the disease. Since 1979, behavioral scientist Nancy Wexler and a team of researchers have been studying the largest known extended family in the world afflicted by Huntington's disease, in small villages in Venezuela. The villagers have cooperated with the research, partly because Wexler

Text not available due to copyright restrictions

herself lost her mother, three uncles, and her maternal grandfather to Huntington's disease, and she, too, may develop the disorder (Wexler & Rawlins, 2005). Using genetic linkage analysis techniques (see Chapter 4), these researchers first mapped the deficit to an area on chromosome 4 (Gusella et al., 1983) and then identified the elusive gene (Huntington's Disease Collaborative Research Group, 1993). Finding that one gene causes a disease is exceptional; research on other inherited mental disorders typically points to multiple gene (polygenic) influences.

**Pick's disease** is a rare neurological condition—occurring in about 5% of those people with dementia—that produces a cortical dementia similar to that of Alzheimer's disease. The course of this disease is believed to last from 5 to 10 years, although its cause is as yet unknown (Richards & Sweet, 2009). Like Huntington's disease, Pick's disease usually occurs relatively early in life—during a person's 40s or 50s—and is therefore considered an example of presenile dementia. An even rarer condition, **Creutzfeldt-Jakob disease**, is believed to affect only one in every million individuals (Heath et al., 2010). An alarming development in the study of Creutzfeldt-Jacob disease is the finding of 10 cases of a new variant that may be linked to bovine spongiform encephalopathy, more commonly referred to as "mad cow disease" (Neugroschi et al., 2005). This discovery led to a ban on exporting beef from the United Kingdom because the disease might be transmitted from infected cattle to humans. We do not yet have definitive information about the link between mad cow disease and the new form of Creutzfeldt-Jacob disease (Wiggins, 2009).

## Substance-Induced Persisting Dementia

Prolonged drug use, especially combined with poor diet, can damage the brain and, in some circumstances, can lead to dementia. This impairment unfortunately lasts beyond the period involved in intoxication or withdrawal from these substances.

### Description and Statistics

As many as 7% of individuals dependent on alcohol meet the criteria for dementia (Neugroschi et al., 2005). *DSM-IV-TR* identifies several drugs that can lead to symptoms of dementia, including alcohol, inhalants such as glue or gasoline (which some people inhale for the euphoric feeling they produce), and sedative, hypnotic, and anxiolytic drugs (see Chapter 11). These drugs pose a threat because they create dependence, making it difficult for a user to stop ingesting them. The resulting brain damage can be permanent and can cause the same symptoms as seen in dementia of the Alzheimer's type. The *DSM-IV-TR* criteria for substance-induced persisting dementia are essentially the same as those for the other forms of dementia; they include memory impairment and at least one of the following cognitive disturbances: aphasia (language disturbance), apraxia (inability to carry out motor activities despite intact motor function), agnosia (failure to recognize or identify objects despite intact sensory function), or a disturbance in executive functioning (such as planning, organizing, sequencing, and abstracting).

## Causes of Dementia

As our technology for studying the brain advances, so does our understanding of the many and varied causes of dementia. A complete description of what is known about the origins of this type of brain impairment is beyond the scope of this book, but we highlight some insights available for more common forms of dementia.

### Biological Influences

Cognitive abilities can be adversely compromised in many ways. As you have seen, de-

mentia can be caused by a number of processes: Alzheimer's disease, Huntington's disease, Parkinson's disease, head trauma, substance abuse, and others. The most common cause of dementia, Alzheimer's disease, is also the most mysterious. Because of its prevalence and our relative ignorance about the factors responsible for it, Alzheimer's disease has held the attention of many researchers, who are trying to find the cause and ultimately a treatment or cure for this devastating condition.

Findings from Alzheimer's research seem to appear almost daily. We should be cautious when interpreting the output of this fast-paced and competitive field; too often, as you have seen in other areas, findings are heralded prematurely as conclusive and important. Remember that "discoveries" of a single gene for bipolar disorder, schizophrenia, and alcoholism were later shown to be based on overly simplistic accounts. Similarly, findings from Alzheimer's research are sometimes too quickly sanctioned as accepted truths before they have been replicated, an essential validation process.

One lesson in scientific caution comes from research that demonstrates a negative correlation between cigarette smoking and Alzheimer's disease (Brenner et al., 1993). In other words, the study found that smokers are less likely than nonsmokers to develop Alzheimer's disease. Does this mean smoking has a protective effect, shielding a person against the development of this disease? On close examination, the finding may instead be the result of the differential survival rates of those who smoke and those who do not. In general, nonsmokers tend to live longer and are thereby more likely to develop Alzheimer's disease, which appears later in life. Some even believe the relative inability of cells to repair themselves, a factor that may be more pronounced among people with Alzheimer's disease, may interact with cigarette smoking to shorten the lives of smokers who are at risk for Alzheimer's disease (Riggs, 1993). Put another way, smoking may exacerbate the degenerative process of Alzheimer's disease, causing people with the disease who also smoke to die earlier than nonsmokers who have Alzheimer's disease. These types of studies and the conclusions drawn from them should make us sensitive to the complicated nature of the disorders.

What do we know about Alzheimer's disease, the most common cause of dementia? After the death of the patient he described as having a "strange disease of the cerebral cortex," Alois Alzheimer performed an autopsy. He found that the brain contained large numbers of tangled, strandlike filaments within the brain cells (referred to as *neurofibrillary tangles*). This type of damage occurs in everyone with Alzheimer's disease. A second type of degeneration results from gummy protein deposits—called *amyloid plaques* (also referred to as *neuritic* or *senile plaques*)—that accumulate between the neurons in the brains of people with this disorder. Amyloid plaques are also found in older adults who do not have symptoms of dementia, but they have far fewer of them than do individuals with Alzheimer's disease (Richards & Sweet, 2009). Both forms of damage—neurofibrillary tangles and amyloid plaques—accumulate over the years and are believed to produce the characteristic cognitive disorders we have been describing.

These two types of degeneration affect extremely small areas and can be detected only by a microscopic examination of the brain. As mentioned earlier, scientists are close, however, to developing the neuroimaging technology that may soon detect the early development of these types of brain cell damage without having to rely on an autopsy (Weiner et al., 2010). In addition to having neurofibrillary tangles and amyloid plaques, over time the brains of many people with Alzheimer's disease atrophy (shrink) to a greater extent than would be expected through normal aging (Richards & Sweet, 2009). Because brain shrinkage has many causes, however, only by observing the tangles and plaques can a diagnosis of Alzheimer's disease be properly made.

Rapid advances are being made toward uncovering the genetic bases of Alzheimer's disease (e.g., Seshadri et al., 2010). As with most other behavioral disorders we have examined, multiple genes seem to be involved in the development of Alzheimer's disease. Table 15.4 illustrates what we know so far. Genes on chromosomes 21, 19, 14, 12, and 1 have all been linked to certain forms of Alzheimer's disease (Neugroschi et al., 2005). The link to chromosome 21 was discovered first, and it resulted from the unfortunate observation that individuals with Down syndrome, who have three copies of chromosome 21 instead of the usual two, developed the disease at an unusually high rate (Report of the Advisory Panel on Alzheimer's Disease, 1995). More recent work has located relevant genes on other chromosomes. These discoveries indicate that there is more than one genetic cause of Alzheimer's disease. Some forms, including the one associated with chromosome 14, have an early onset. Diana may have an early-onset form, because she started noting symptoms at the age of 45. In contrast, Alzheimer's disease associated with chromosome 19 seems to be a late-onset form of the disease that has an effect only after the age of about 60.

**TABLE 15.4** Genetic Factors in Alzheimer's Disease

| Gene | Chromosome | Age of Onset (years) |
|---|---|---|
| APP | 21 | 43 to 59 |
| Presenilin 1 | 14 | 33 to 60 |
| Presenilin 2 | 1 | 50 to 90 |
| apo E4 | 19 | 60 |
| A2M | 12 | 70 |

A2M = alpha-2-macroglobulin; AAP = amyloid precursor protein; apo E4 = apolipoprotein E4.

Some genes that are now identified are **deterministic**, meaning that if you have one of these genes you have a nearly 100% chance of developing Alzheimer's disease (Bettens, Sleegers, & Van Broeckhoven, 2010). Deterministic genes such as the precursor gene for small proteins called *amyloid beta peptides* (also referred to as beta-amyloid or A(β) and the *Presenilin 1* and *Presenilin 2* genes will inevitably lead to Alzheimer's disease, but, fortunately, these genes are also rare in the general population. For treatment purposes, this means that even if researchers can find a way to prevent these genes from leading to Alzheimer's disease, it will only help a relatively small number of people. On the other hand, some genes—including the *apolipoprotein E4 (apo E4)* gene—are known as **susceptibility** genes. These genes only slightly increase the risk of developing Alzheimer's disease, but in contrast to the deterministic genes, these are more common in the general population (Bettens et al., 2010). If future research can find ways to interfere with the apo E4 gene, many people will be helped.

Although closing in on the genetic origins of Alzheimer's disease has not brought immediate treatment implications, researchers are nearer to understanding how the disease develops, which may result in medical interventions. Genetic research has advanced our knowledge of how the amyloid plaques develop in the brains of people with Alzheimer's disease and may hold a clue to its origins. In the core of the plaques is a solid waxy substance made up of Aβ. Just as cholesterol buildup on the walls of blood vessels chokes the blood supply, deposits of Aβ are believed by some researchers to cause the cell death associated with Alzheimer's disease (Gatz, 2007). An important question, then, is: Why does this protein accumulate in the brain cells of some people but not of others?

Two mechanisms that may account for amyloid protein buildup are being studied. The first involves *amyloid precursor protein* (APP), a large protein that is eventually broken down into the *amyloid protein* found in the amyloid plaques. Important work resulted in identifying the gene responsible for producing APP, on chromosome 21 (Richards & Sweet, 2009). This finding may help integrate two observations about Alzheimer's disease: (1) APP produces the amyloid protein found in the amyloid plaques, and (2) Down syndrome, associated with an extra 21st chromosome, results in a higher incidence of the disease (see Chapter 14). The gene responsible for producing APP and, ultimately, amyloid protein, may be responsible for the relatively infrequent early-onset form of the disease, and its location could explain why people with Down syndrome—who have an extra 21st chromosome and therefore an extra APP gene—are more likely than the general population to develop Alzheimer's disease.

A second, more indirect way that amyloid protein may build up in brain cells is through apolipoprotein E (apo E), which normally helps transport cholesterols, including amyloid protein, through the bloodstream. There are at least three forms of this transporter protein: apo E2, apo E3, and apo E4. Individuals who have late-onset Alzheimer's disease, the most common form, are likely to carry the gene associated with apo E4, located on chromosome 19. Researchers have found that the majority of people with Alzheimer's disease who also have a family history of the disease will have at least one gene for apo E4 (Richards & Sweet, 2009). In contrast, approximately 64% of individuals with Alzheimer's disease who have no family history of the disease have at least one gene for apo E4, and only 31% of nonaffected individuals have the gene. Having two genes for apo E4 (one on each member of the chromosome 19 pair) increases the risk for Alzheimer's disease: As many as 90% of people with two genes developed Alzheimer's disease (Reiman et al., 2007). In addition, having two apo E4 genes seemed to decrease the mean age of onset from 84 years to 68 years. These results suggest that apo E4 may be responsible for late-onset Alzheimer's disease and that a gene on chromosome 19 is responsible. What is still not completely understood is how apo E4 causes amyloid proteins to build up in the neurons of people who ultimately exhibit Alzheimer's disease and whether this process is responsible for the disease.

Researchers are just beginning to try to examine potential gene–environment interactions in Alzheimer's disease. Several isolated studies suggest a few areas of promise. For example, one study found that among African Americans, having low levels of cholesterol seemed to reduce risk of Alzheimer's disease—but only among those who did not carry the apo E4 gene (Evans et al., 2000). In another study, physical exercise reduced the likelihood of developing the disease but, like the previous study, only among those without the apo E4 gene (Podewils et al., 2005). This type of research holds the potential for better understanding the complex nature of Alzheimer's disease and may lead to important prevention strategies (such as lowering cholesterol levels and exercising regularly) (Pedersen, 2010).

For all disorders described in this book, we have identified the role of biological, psychological, or both types of stressors as partially responsible for the onset of the disorder. Does dementia of the Alzheimer's type—which appears to be a strictly biological event—follow the same pattern? One of the leading candidates for an external contributor to this disorder is head trauma. As we have seen, it appears that repeated blows to the head can bring on *dementia pugilistica,* named after the boxers who suffer from this type of dementia. Fighters who carry the apo E4 gene may be at greater risk for developing dementia attributed to head trauma (Jordan et al., 1997). In addition to boxers, news accounts suggest links to the trauma experienced by NFL players and the development of dementia in these former athletes (Schwarz, 2007). Because it is now known that not only boxers are affected by this type of dementia, the disorder is now termed *chronic traumatic encephalopathy (CTE).* Head trauma may be one of the stressors that initiates the onset of dementias of varying types. Other such stressors include having diabetes, high blood pressure, or herpes simplex virus-1 (Richards & Sweet, 2009). As with each of the disorders discussed, psychological and biological stressors may interact with physiological processes to produce Alzheimer's disease.

We opened the section with a word of caution, which it is appropriate at this point to repeat. Some of the findings just reviewed are considered controversial, and many questions remain to be answered about dementia and one of its most common causes, Alzheimer's disease.

### Psychological and Social Influences

Research has mostly focused on the biological conditions that produce dementia. Although few would claim that psychosocial influences directly cause the type of brain deterioration seen in people with dementia, they may help determine onset and course. For example, a person's lifestyle may involve contact with factors that can cause dementia. You saw, for instance, that substance abuse can lead to dementia and, as we discussed previously (see Chapter 11), whether a person abuses drugs is determined by a combination of biological and psychosocial factors. In the case of vascular dementia, a person's biological vulnerability to vascular disease will influence the chances of strokes that can lead to this form of dementia. Lifestyle issues such as diet, exercise, and stress influence cardiovascular disease and therefore help determine who experiences vascular dementia (see Chapter 9).

Cultural factors may also affect this process. For example, hypertension and strokes are prevalent among African Americans and certain Asian Americans (King, Mainous III, & Geesey, 2007), which may explain why vascular dementia is more often observed in members of these groups. In an extreme example, exposure to a viral infection can lead to dementia similar in form to Creutzfeldt-Jakob disease through a condition known as kuru. This virus is passed on through a ritual form of cannibalism practiced in Papua New Guinea as a part of mourning (Collinge et al., 2006). Dementia caused by head trauma and malnutrition are relatively prevalent in preindustrial rural societies (Del Parigi, Panza, Capurso, & Solfrizzi, 2006). Not getting enough of vitamins $B_9$ and $B_{12}$ in particular seems to lead to dementia, although the process is as yet unknown. These findings suggest that occupational safety (such as protecting workers from head injuries) and economic conditions influencing diet also affect the prevalence of certain forms of dementia. It is apparent that psychosocial factors help influence who does and who does not develop certain forms of dementia. Brain deterioration is a biological process but, as you have seen throughout this text, even biological processes are influenced by psychosocial factors.

Psychosocial factors themselves influence the course of dementia. Recall that educational attainment may affect the onset of dementia (Richards & Sweet, 2009). Having certain skills may help some people cope better than others with the early stages of dementia. As you saw earlier, Diana's mother was able to carry on her day-to-day activities by making maps and using other tricks to help compensate for her failing abilities. The early stages of confusion and memory loss may be better tolerated in cultures with lowered expectations of older adults. In certain cultures, including the Chinese, younger people are expected to take the demands of work and care from older adults after a certain age, and symptoms of dementia are viewed as a sign of normal aging (Gallagher-Thompson et al., 2006; Hinton, Guo, Hillygus, & Levkoff, 2000). Dementia may go undetected for years in these societies.

Much remains to be learned about the cause and course of most types of dementia. As you saw with Alzheimer's disease and Huntington's disease, certain genetic factors make some individuals vulnerable to progressive cognitive deterioration. In addition, brain trauma, some diseases, and exposure to certain drugs, such as alcohol, inhalants, and sedative, hypnotic, and anxiolytic drugs, can cause the characteristic decline in cognitive abilities. We also noted that psychosocial factors can help determine who is subject to these causes and how they cope with the condition. Looking at dementia from this integrative perspective should help you view treatment approaches in a more optimistic light. It may be possible to protect people from conditions that lead to dementia and to support them in dealing with the devastating consequences of having it. We next review attempts to help from both biological and psychosocial perspectives.

## Treatment

For many of the disorders discussed in other chapters, treatment prospects are fairly good. Clinicians can combine various strategies to reduce suffering significantly. Even when treatment does not bring expected improvements, mental health professionals have usually been able to stop problems from progressing. This is not the case in the treatment of dementia.

One factor preventing major advances in the treatment of dementia is the nature of the damage caused by this disorder. The brain contains billions of neurons, many more than are used. Damage to some can be compensated for by others because of plasticity. However, there is a limit to where and how many neurons can be destroyed before vital functioning is disrupted. Researchers are closing in on how to use the brain's natural process of regeneration to potentially reverse the damage caused in dementia (Khachaturian, 2007). Currently, however, with extensive brain damage, no known treatment can restore lost abilities. The goals of treatment therefore become (1) trying to prevent certain conditions, such as substance abuse, that may bring on dementia; (2) trying to delay the onset of symptoms to provide better quality of life; and (3) attempting to help these individuals and their caregivers cope with the advancing deterioration. Most efforts in treating dementia have focused on the second and third goals, with biological treatments aimed at stopping the cerebral deterioration and psychosocial treatments directed at helping patients and caregivers cope.

A troubling statistic further clouds the tragic circumstances of dementia: More than 23% of caregivers of people with dementia—usually relatives—have the symptoms characteristic of one or more anxiety disorders and 10% are clinically depressed (Katona & Livingston, 2009). Compared with the public, these caregivers use more psychotropic medications (designed to reduce symptoms of various psychological disorders) and report stress symptoms at 3 times the normal rate. Caring for people with dementia, especially in its later stages, is clearly a trying experience. In fact, there is some evidence to suggest that the stress associated with caring for a person with dementia may place the caregiver at greatly increased risk for developing dementia themselves (Norton et al., 2010). As a result, clinicians are becoming increasingly sensitive to the needs of these caregivers, and research is now exploring interventions to assist them in caring for people with dementia (Lee, Czaja, & Schulz, 2010).

### *Biological Treatments*

Dementia resulting from known infectious diseases, nutritional deficiencies, and depression can be treated if it is caught early. Unfortunately, however, no known treatment exists for most types of dementia that are responsible for the vast majority of cases. Dementia caused by stroke, HIV, Parkinson's disease, or Huntington's disease is not currently treatable because there is no effective treatment for the primary disorder. However, exciting research in several related areas has brought us closer to helping individuals with these forms of dementia. A substance that may help preserve and perhaps restore neurons—called glial cell–derived neurotrophic factor—may someday be used to help reduce or reverse the progression of degenerative brain diseases (Zuccato & Cattaneo, 2009). Researchers are also looking into the possible benefits of transplanting stem cells (fetal brain tissue) into the brains of people with such diseases. Initial results from these studies are still preliminary but appear promising (Arenas, 2010). Dementia brought on by strokes may now be more preventable by new drugs that help prevent much of the damage inflicted by the blood clots characteristic of stroke (Richards & Sweet, 2009). Most current attention is on a treatment for dementia of the Alzheimer's type, because it affects so many people. Here, too, however, success has been modest at best.

Much work has been directed at developing drugs that will enhance the cognitive abilities of people with dementia of the Alzheimer's type. Many seem to be effective initially, but long-term improvements have not been observed in placebo-controlled studies (Richards & Sweet, 2009). Several drugs (called *cholinesterase inhibitors*) have had a modest impact on cognitive abilities in some patients and include donepezil (Aricept), rivastigmine (Exelon), and galantamine (Reminyl). *Tacrine hydrochloride* (Cognex), another in this family of drugs, is rarely used today because of the potential for liver damage (Rabins, 2006). These drugs prevent the breakdown of the neurotransmitter acetylcholine (which is deficient in people with Alzheimer's disease), thus making more acetylcholine available to the brain. Research suggests that, when using these drugs, people's cognitive abilities improve to the point where they were 6 months earlier (Lyketos, 2009). But the gain is not permanent. Even people who respond positively do not stabilize but continue to experience the cognitive decline associated with Alzheimer's disease. In addition, if they stop taking the drug—as almost three-quarters of the patients do because of negative side effects such as liver damage and nausea—they lose even that 6-month gain (Lyketos, 2009). Newer drugs are now being investigated for the treatment of Alzheimer's disease. These include drugs that target the beta-amyloid (plaques) in the brain, and it is hoped that these advances will finally provide a positive prognosis for this devastating disease (Rafii & Aisen, 2009).

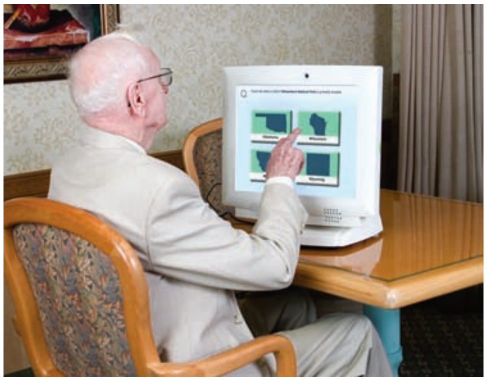
Several other medical approaches are being explored to slow the course of Alzheimer's disease, but initial excitement generated by these approaches has waned with the findings from researchers. For example, most of you have heard of using *Ginkgo biloba* (maidenhair) to improve memory. Initial research suggested that this herbal remedy may produce modest improvements in the memory of people with Alzheimer's disease, but other studies have not replicated this benefit (DeKosky et al., 2008). Similarly, the effects of vitamin E have been evaluated. One large study found that among individuals with moderately severe impairment, high doses of the vitamin (2,000 international units per day) delayed progression compared to a placebo (Sano et al., 1997), but it did not prevent the development of the disease. Further research, in fact, indicates that taking high doses of vitamin E may actually increase mortality and therefore this intervention is no longer recommended (Richards & Sweet, 2009). Modest slowing of the progression of the disease also may be obtained by introducing exercise to patients (Rockwood & Middleton, 2007; Teri et al., 2003). To date, however, no medical interventions are available that directly treat and therefore stop the progression of the conditions that cause the cerebral damage in Alzheimer's disease.

Medical interventions for dementia also include the use of drugs to help with some associated symptoms. A variety of antidepressants—such as serotonin-specific reuptake inhibitors—are commonly recommended to alleviate the depression and anxiety that too often accompany the cognitive decline. Antipsychotic medication is sometimes used for those who become unusually agitated (Richards & Sweet, 2009). Next we describe psychosocial approaches that are used with medication to address the variety of problems that accompany memory difficulties.

### *Psychosocial Treatments*

Psychosocial treatments are now receiving a great deal of attention for their ability to delay the onset of severe cognitive decline. These efforts focus on enhancing the lives of people with dementia, as well as those of their families.

People with dementia can be taught skills to compensate for their lost abilities. Recall that Diana's mother learned on her own to make maps to help her get from place to place. Diana herself began making lists so that she would not forget important things. Some researchers have evaluated more formal adaptations to help people in the early stages of dementia. Michelle Bourgeois (2007) created "memory wallets" to help people with dementia carry on conversations. On white index cards inserted into a plastic wallet

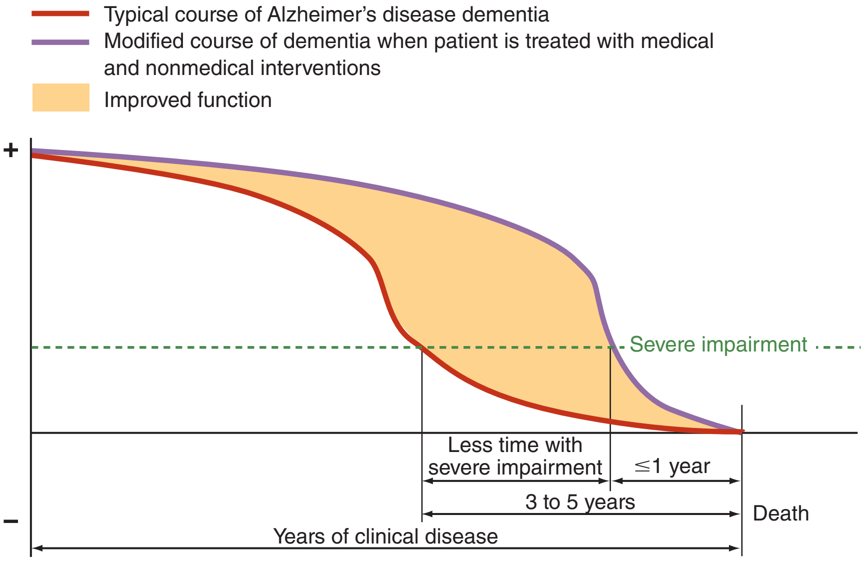


©Dakim [m]Power Cognitive Fitness Systems: Kara Kenna photographer. www.dakim.com

▲ A resident of an assistive living facility practices cognitive stimulation using one of several computer-based systems (the Dakim [m]Power Brain Fitness System).

are printed declarative statements such as, “My husband John and I have 3 children,” or “I was born on January 6, 1921, in Pittsburgh.” In one of her studies, Bourgeois (1992) found that adults with dementia could, with minimal training, use this memory aid to improve their conversations with others. Adaptations such as these help people communicate with others, help them remain aware of their surroundings, and can reduce the frustration that comes with the awareness of their own decline.

Cognitive stimulation—encouraging people with dementia to practice learning and memory skills—seems to be an effective method for delaying the onset of the more severe cognitive effects of this disorder (Knowles, 2010). These activities include word games, tests of memory of famous and familiar faces, and practice with numbers (for example, how much change back you would receive from a purchase). These types of skill-building exercises can maintain cognitive activity and improve the quality of life in those patients when compared to controls.



■ **FIGURE 15.1** Improving the course of Alzheimer’s disease with medical and nonmedical interventions. (From Becker, J. T., Mestre, L. T., Ziolko, S., & Lopez, O. L. (2007). Gene–environment interactions with cognition in late life and compression of morbidity. *American Journal of Psychiatry, 164,* 849–852.)

What impact do the medical and nonmedical treatments have on those with Alzheimer’s disease? ■ Figure 15.1 illustrates how these interventions may delay the worst of the symptoms—essentially compressing the time when the person is most impaired (Becker, Mestre, Ziolko, Lopez, 2007). The red line illustrates the typical course of the disease, which results in 3 to 5 years of severe impairment before death. However, with the interventions we highlighted (illustrated by the blue line), people are able to live more fully for a longer period, despite the still-inevitable impairment and death. Families find this extra time with their loved ones to be invaluable, and hopefully with more advancements we will see progress on improving mortality rates of this progressive disease.

Individuals with advanced dementia are not able to feed, bathe, or dress themselves. They cannot communicate with or recognize even familiar family members. They may wander away from home and become lost. Because they are no longer aware of social stigma, they may engage in public displays of sexual behavior, such as masturbation. They may be frequently agitated or even physically violent. To help both the person with dementia and the caregiver, researchers have explored interventions for dealing with these consequences of the disorder (Richards & Sweet, 2009). For example, some research indicates that a combination of exercise for patients and instruction for caregivers on how to handle behavior problems can improve the overall health and the depression in people with Alzheimer’s disease (Logsdon, McCurry, Pike, & Teri, 2009; Teri et al., 2003).

Of great concern is the tendency of people with dementia to wander. Sometimes they wind up in places or situations that may be dangerous (for example, stairwells or the street). Often, the person is tied to a chair or bed, or sedated, to prevent roaming. Unfortunately, physical and medical restraint has its own risks, including additional medical complications; it also adds greatly to the loss of control and independence that already plague the person with dementia. Psychological treatment as an alternative to restraint sometimes involves providing cues for people to help them safely navigate around their home or other areas. New innovations in surveillance technology—creating a “smart home” that can monitor the location of the patient and warn caregivers—may provide more piece of mind for those who care for these patients. At the same time, ethical concerns are being raised about the use of this technology because of its ability to invade privacy (Bharucha et al., 2009; Mahoney et al., 2007).

Someone with dementia can become agitated and sometimes verbally and physically aggressive. This behavior is understandably stressful for people trying to provide care. In these situations, medical intervention is often used, although many times with only modest results (Testad, Ballard, Brønnick, & Aarsland,

Text not available due to copyright restrictions

2010). Caregivers are often given assertiveness training to help them deal with hostile behaviors (see Table 15.5). Otherwise, caregivers may either passively accept all criticism inflicted by the person with dementia, which increases stress, or become angry and aggressive in return. This last response is of particular concern because of the potential for elder abuse. Withholding food or medication or inflicting physical abuse is most common among caregivers of elderly people who have cognitive deficits (Post, Page, Conner, & Prokhorov, 2010). It is important to teach caregivers how to handle stressful circumstances so that they do not escalate into abusive situations. Not a great deal of objective evidence supports the usefulness of assertiveness training for reducing caregiver stress, and more research is needed to guide future efforts.

In general, families of people with dementia can benefit from supportive counseling to help them cope with the frustration, depression, guilt, and loss that take a heavy emotional toll. However, clinicians must first recognize that the ability to adapt to stressors differs among people. One study, for example, found cultural differences in the coping styles of caregivers. In one area of rural Alabama, white caregivers used acceptance and humor as coping strategies, and black caregivers used religion and denial (Kosberg, Kaufman, Burgio, Leeper, & Sun, 2007). Another large-scale study of 555 principal caregivers over a 3-year period identified a number of steps that can be taken to support caregivers through this difficult time (Aneshensel, Pearlin, Mullan, Zarit, & Whitlatch, 1995). However, despite numerous studies aimed at supporting caregivers, the results to date remain weak and additional work is needed to determine how best to support these individuals (Schoenmakers, Buntinx, & DeLepeleire, 2010).

Early on, caregivers need basic information on the causes and treatment of dementia, financial and legal issues, and locating help for the patient and the family. As the dementia progresses, and the affected person requires increasing amounts of assistance, caregivers will need help managing behavioral difficulties (wandering away or violent outbursts) and developing effective ways to communicate with the patient. Clinicians also assist the family with decisions about hospitalizations and, finally, help them adjust during bereavement (Peeters, Van Beek, Meerveld, Spreeuwenberg, & Francke, 2010).

Overall, the outlook for slowing (but not stopping) the cognitive decline characteristic of dementia is optimistic. The best available medications provide some recovery of function, but they do not stop the progressive deterioration. Psychological interventions may help people cope more effectively with the loss of cognitive abilities, especially in the earlier stages of this disorder. In addition, emphasis is placed on helping caregivers—the other victims of dementia—as the person they care for continues to decline.

## Prevention

Without treatment, we need to rely even more heavily on prevention strategies for dementia. You can imagine that it is difficult to study prevention efforts for dementia because of the need to follow individuals for long periods to see whether the efforts are effective. One major study conducted in Sweden—where socialized medicine provides complete medical histories of all residents—looked at many of the risk factors (those factors that increase the chance of having dementia) and protective factors (those that decrease the risk) under study today (Fratiglioni, Winblad, & von Strauss, 2007). They looked at the medical records of 1,810 participants who were older than 75 at the time and followed them for about 13 years. Through interviews and medical histories, they came to two major conclusions: control your blood pressure, and lead an active physical and social life! These two recommendations came out as the major factors that individuals can change—because you cannot change your genetics, for example—that will decrease the chances of developing dementia. Additional prevention research is ongoing, and there may be other potentially fruitful research areas that can lead to the successful prevention of this devastating disorder.

**Innovative Approaches**

## Are We Close to an Alzheimer's Vaccine?

We described in Chapter 11 how researchers are striving to create a vaccine that would use the immune system to fight drugs such as heroin, just as your body attacks infectious bacteria. Other researchers are targeting vaccines that would potentially treat and prevent—rather than just delay—the symptoms of Alzheimer's disease. Much of the research is attempting to get the immune system to attack the process that overproduces the small proteins (Aβ) that lead to cell death. Prior efforts had to be abandoned because of the severe negative side effects of the vaccine, which included serious brain inflammation. More recent research with humans and animals indicates that there may be several vaccines that could be effective in preventing the damage caused by Aβ formation and therefore represent the first glimmer of hope for patients and their families (Subramanian, Bandopadhyay, Mishra, Mathew, & John, 2010).

This type of research currently begins with transgenic mice—mice in which the DNA has been altered. In the case of testing an Alzheimer's vaccine, the mice DNA is engineered to produce the same small proteins thought to be responsible for the dementia. Mice are good subjects because they age rapidly, with a 22-month-old mouse equivalent to a 65-year-old human (Morgan, 2007). This allows researchers to study how the brain reacts to the potential vaccine if it has already started the progression of Alzheimer's. If the results are promising in these transgenic mice, only then do researchers try small studies with humans. Researchers are optimistic that there may finally be intervention approaches that would reverse the current trend of increasing numbers of people with dementia.

## Concept Check 15.2

### Part A

Identify the following symptoms of dementia from the descriptions: (a) facial agnosia, (b) agnosia, and (c) aphasia.

1. Timmy's elderly grandmother does not recognize her own home any more. ____________
2. She can no longer form complete, coherent sentences. ____________
3. She no longer recognizes Timmy when he visits, even though he is her only grandchild. ____________

### Part B

Identify the cognitive disorders described.

4. Julian is a recovering alcoholic. When asked about his wild adventures as a young man, his stories usually end quickly because he can't remember the whole tale. He even has to write down things he has to do in a notebook; otherwise, he's likely to forget. ____________
5. Mr. Brown has suffered from a number of strokes but can still care for himself. However, his ability to remember important things has been declining steadily for the past few years. ____________
6. A decline in cognitive functioning that is gradual and continuous and has been associated with neurofibrillary tangles and amyloid plaques. ____________

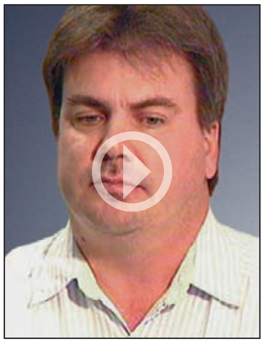
## Amnestic Disorder

Say these three words to yourself: *apple, bird, roof.* Try to remember them, and then count backward from 100 by 3s. After about 15 seconds of counting, can you still recall the three words? Probably so. However, people with **amnestic disorder** will not remember them, even after such a short period (Bourgeois, Seaman, & Servis, 2008). The loss of this type of memory, which we described as a primary characteristic of dementia, can occur without the loss of other high-level cognitive functions. The main deficit of amnestic disorder appears to be the inability to transfer information like the list we just described into long-term memory, which can cover minutes, hours, or years. This disturbance in memory is caused by either the physiological effects of a medical condition, such as head trauma, or the long-term effects of a drug. Consider the case of S. T.

### **S. T.** *Remembering Fragments*

S. T., a 67-year-old white woman, suddenly fell, without loss of consciousness. She appeared bewildered and anxious but oriented to person and place. Language functioning was normal. Yet she was not oriented to time. She was unable to recall her birthplace, the ages of her children, or any recent presidents of the United States. She could not remember three objects for 1 minute, nor recall what she had eaten for her last meal. She could not name the color of any object shown to her but could correctly name the color related to certain words—for example, *grass* and *sky.* Object naming was normal. Examined 1 year later, she could repeat five digits forward and backward but could not recall her wedding day, the cause of her husband's death, or her children's ages. She did not know her current address or phone number and remembered none of three objects after 5 minutes. While she was described by her family as extremely hard-working before her illness, after hospitalization she spent most of her time sitting and watching television. She was fully oriented, displayed normal language function, and performed simple calculations without error (Cole, Winkelman, Morris, Simon, & Boyd, 1992, pp. 63–64).

The *DSM-IV-TR* criteria for amnestic disorder describe the inability to learn new information or to recall previously learned information. As with all cognitive disorders, memory disturbance causes significant impairment in social and occupational functioning. The woman just described was diagnosed with a type of amnestic disorder called *Wernicke-Korsakoff syndrome,* which is caused by damage to the thalamus, a small region deep inside the brain that acts as a relay station for information from many other parts of the brain. In her case, the damage to the thalamus was believed to be the result of a stroke that caused vascular damage. Another common cause of Wernicke-Korsakoff syndrome is chronic heavy alcohol use.



© Cengage Learning

### Amnestic Disorder: Mike

*"I still have a pretty major memory problem, which has since brought about a divorce and which . . . I now have a new girlfriend, which helps very much. I even call her . . . my new brain or my new memory. . . . If I want to know something, besides on relying on this so-called memory notebook, which I jot notes down in constantly and have it every day dated, so I know what's coming up or what's for that day. She also helps me very much with the memory. My mother types up the pages for this notebook, which has each half hour down and the date, the day and the date, which anything coming within an hour or two or the next day or the next week, I can make a note of it so that when that morning comes, and I wake up, I right away, one of the first things, is look at the notebook. What have I got to do today?"*

**Go to Psychology CourseMate at www.cengagebrain.com to watch this video.**

S. T. had pronounced difficulty recalling information presented just minutes before. Although she could repeat a series of numbers, she couldn't remember three objects presented to her a few minutes earlier. As with other people with amnestic disorder, despite these obvious deficits with her memory, her language command was fine and she could perform simple chores. Yet these individuals are often significantly impaired in social or vocational functioning because of the importance of memory to such activities.

As you saw with the other cognitive impairments, a range of traumas to the brain can cause permanent amnestic disorders. Research has focused on attempting to prevent the damage associated with Wernicke-Korsakoff syndrome. Specifically, a deficiency in thiamine (vitamin $B_1$) resulting from alcohol abuse in people developing Wernicke-Korsakoff syndrome is leading researchers to try supplementing this vitamin, especially for heavy drinkers (Sechi & Serra, 2007). To date, however, there is little research pointing to successful long-term assistance in treating people with amnestic disorders (Bourgeois et al., 2008).

### DSM-IV-TR

### Table 15.6 Diagnostic Criteria for Amnestic Disorder Due to . . . [Indicate the General Medical Condition]

**A.** The development of memory impairment as manifested by impairment in the ability to learn new information or the inability to recall previously learned information.

**B.** The memory disturbance causes significant impairment in social or occupational functioning and represents a significant decline from a previous level of functioning.

**C.** The memory disturbance does not occur exclusively during the course of a delirium or a dementia.

**D.** There is evidence from the history, physical examination, or laboratory findings that the disturbance is the direct physiological consequence of a general medical condition (including physical trauma).

Specify if:

Transient: If memory impairment lasts for 1 month or less

Chronic: If memory impairment lasts for more than 1 month

*Source:* Reprinted, with permission, from American Psychiatric Association. (2000). *Diagnostic and statistical manual of mental disorders* (4th ed., text revision). Washington, DC: Author, © 2000 American Psychiatric Association.

### Concept Check 15.3

Insert either a T for true or an F for false for these statements pertaining to amnestic disorder.

1. ___ Amnestic disorder refers to the inability to learn new information or to recall previously learned information.
2. ___ *Ginkgo biloba* has been found to be effective in treating amnestic disorders.
3. ___ Amnestic disorders can be either transient, lasting 1 month or less, or chronic, lasting more than 1 month.
4. ___ The abuse of alcohol and trauma to the brain can cause amnestic disorders.

## On the Spectrum

### Toward a Dimensional Approach to Cognitive Disorders

Discussions about any changes in the category of cognitive disorders in *DSM-5* are focused on ways to incorporate a dimensional approach. Although there are as yet no final changes, one of the proposals is to separate the disorders involving dementia and amnesia into Major and Minor Neurocognitive Disorders categories (American Psychiatric Association, 2010). The distinction between "major" and "minor" neurocognitive disorders is a difficult one to make, although it is assumed that minor cognitive deficits would include problems such as memory difficulties that are not sufficient to interfere with the person's ability to live independently. The neurocognitive disorders would be defined based on a decline from a previous level of cognitive functioning, which would include the loss of a person's ability to carry out important daily living activities independently (for example, cooking, dressing, etc.).

This proposed distinction is consistent with some of the breakthroughs in diagnoses involving improved brain scanning that we covered earlier in this chapter (Weiner et al., 2010). Researchers are becoming more sophisticated in their ability to identify beginning signs of dementia, which not only allows for early diagnosis (e.g., minor neurocognitive disorder) but also can highlight for clinicians the need to track cognitive abilities over time. It is important to monitor cognitive abilities to see if the changes remain stable (as you would see in traumatic brain injury or stroke), if they improve (which can occur with dementia related to properly treated HIV or substance abuse), or if they continue to decline (such as with Alzheimer's disease). This is a beginning step designed to assist diagnostic efforts by including a dimensional approach to identifying the range of neurocognitive disorders (such as dementia and amnestic disorder). For example, being able to identify minor problems may someday lead to differential treatment, along the lines of the Alzheimer's vaccine discussed previously.

# Summary

### Delirium

- Delirium is a temporary state of confusion and disorientation that can be caused by brain trauma, intoxication by drugs or poisons, surgery, and a variety of other stressful conditions, especially among older adults.

### Dementia

- Dementia is a progressive and degenerative condition marked by gradual deterioration of a range of cognitive abilities including memory, language, and planning, organizing, sequencing, and abstracting information.
- Alzheimer's disease is the leading cause of dementia, affecting approximately 4 million Americans; there is currently no known cause or cure.
- To date, there is no effective treatment for the irreversible dementias caused by Alzheimer's disease, Parkinson's disease, Huntington's disease, and various less common conditions that produce this progressive cognitive impairment. Treatment often focuses on helping patients cope with the continuing loss of cognitive skills and helping caregivers deal with the stress of caring for affected individuals.

### Amnestic Disorder

- Amnestic disorders involve a dysfunction in the ability to recall recent and past events. The most common is Wernicke-Korsakoff syndrome, a memory disorder usually associated with chronic alcohol abuse.

# Exploring Cognitive Disorders

- When the brain is damaged, the effects are irreversible, accumulating until learning, memory, or consciousness are obviously impaired.
- Cognitive disorders develop much later than intellectual disability and other learning disorders, which are believed to be present at birth.

## TYPES OF COGNITIVE DISORDERS

| | | Description | Causes (subtypes) | Treatment |
|---|---|---|---|---|
| **Delirium** |  ©Photodisc/Getty Images | • Impaired consciousness and cognition for several hours or days<br>– confusion, disorientation, inability to focus<br>• Most prevalent among older adults, people with AIDS, and patients on medication | • Delirium due to a general medical condition<br>• Substance-induced delirium<br>• Delirium due to multiple etiologies<br>• Delirium not otherwise specified | • Pharmacological<br>– benzodiazepines<br>– antipsychotics<br>• Psychosocial<br>– reassurance<br>– presence of personal objects<br>– inclusion in treatment decisions |

©Photodisc/Getty Images

| | | Description | Causes | Treatment |
|---|---|---|---|---|
| **Amnestic Disorder** | ©Photodisc/Getty Images | • Permanent short-term memory loss without impairment of other cognitive functions<br>– inability to learn new information or recall previously learned information<br>– significant impairment in social and occupational functioning | • Medical condition such as head trauma<br>• Lasting effects of a drug, even after the substance is no longer ingested | • Prevention: proper medical care and drug monitoring<br>• No long-term success at combating damage |

**Subtype**

**Wernicke/Korsakoff Syndrome**

Caused by damage to the thalamus from injury (stroke) or chronic heavy alcohol use (thiamine depletion)

# Dementia

- Gradual deterioration of brain functioning that affects judgment, memory, language, and other advanced cognitive processes
- Caused by medical condition or drug abuse
- Some forms are irreversible, some are resolved by treatment of primary condition.

## TYPES OF DEMENTIA

| | | Description | Causes | Treatment |
|---|---|---|---|---|
| **Dementia of the Alzheimer's Type** |  ©Gabriela Medina/Blend Images/Jupiter Images | • Increasing memory impairment and other multiple behavioral and cognitive deficits, affecting language, motor functioning, ability to recognize people or things, and/or planning<br>• Most prevalent dementia<br>• Subject of most research | • Progressive brain damage, evident in neurofibrillary tangles and neuritic plaque, confirmed by autopsy but assessed by simplified mental status exam<br>• Involves multiple genes | • No cure so far, but hope lies in genetic research and amyloid protein in neurine plaques.<br>• Management may include lists, maps, and notes to help maintain orientation.<br>• New medications that prevent acetylcholine breakdown and vitamin therapy show promise. |
| **Substance-induced Persisting Dementia** | ©Photodisc/Getty Images | • Caused by brain damage due to prolonged drug use, especially in combination with poor diet, as in alcohol dependency; other substances may include inhalants, and the sedative, hypnotic, and anxiolytic drugs<br>• Treatment focuses on prevention. | | |
| **Vascular Dementia** | ©Photodisc/Getty Images | • Permanent deterioration due to blocked or damaged blood vessels in the brain (stroke)<br>• Symptoms identical to Alzheimer's and may also include problems with walking and weakness of limbs<br>• Treatment focuses on coping. | | |
| **Dementia Due to Other General Medical Conditions** | ©Harmut Schwarzbach/Peter Arnold | • Similar in effect to other cognitive disorders, but caused by:<br>– head trauma<br>– HIV, Parkinson's, Huntington's, Pick's, or Creutzfeldt-Jakob disease<br>– hydrocephalus, hypothyroidism, brain tumor, and vitamin B12 deficiency<br>• Treatment of primary condition is sometimes possible. | | |

* Portions of this chapter cover learning outcomes suggested by the American Psychological Association (2007) in their guidelines for the undergraduate psychology major. Chapter coverage of these outcomes is identified above by APA Goal and APA Suggested Learning Outcome (SLO).

## Perspectives on Mental Health Law

We begin this chapter with a return to Arthur, whom we described in Chapter 13 as having psychotic symptoms. Revisiting the case from his family's perspective reveals the complexities of mental health law and the ethical aspects of working with people who have psychological disorders.

### ARTHUR | *A Family's Dilemma*

As you remember, Arthur was brought to our clinic by family members because he was speaking and acting strangely. He talked incessantly about his "secret plan" to save all the starving children in the world. His family's concern intensified when Arthur said he was planning to break into the German embassy and present his plan to the German ambassador. Alarmed by his increasingly inappropriate behavior and fearing he would be hurt, the family was astounded to learn they could not force him into a psychiatric hospital. Arthur could admit himself—which was not likely, given his belief that nothing was wrong with him—but they had no power to admit him involuntarily unless he was in danger of doing harm to himself or others. Even if they sincerely believed some harm might be forthcoming, this wasn't sufficient reason to admit him involuntarily. The family coped with this emergency as best they could for several weeks until the worst of Arthur's behaviors began to diminish.

Arthur suffered from what is known as brief psychotic disorder (see Chapter 13). Fortunately for him, this is one of the few psychotic disorders that is not chronic. What is important here is to see how the mental health system responded. Because Arthur had not hurt himself or someone else, he had to seek help on his own before the hospital would assist him, even though everyone involved realized that such action on his part was unlikely. This response by the mental health system added one more layer of helplessness to the family's already desperate emotional state. Why wouldn't the mental health facility admit Arthur, who was clearly out of touch with reality and in need of help? Why couldn't his own family authorize the mental health facility to act? What would have happened if Arthur had entered the German embassy and hurt or, worse, killed someone? Would he have gone to jail, or would he have finally received help from the mental health community? Would Arthur have been held responsible if he hurt other people while he was delusional? These are just a few of the many issues that surface when we try to balance the rights of people who have psychological disorders with the responsibilities of society to provide care.

Mental health professionals face such questions daily. They must both diagnose and treat people and consider individual and societal rights and responsibilities. As we describe how systems of ethics and legal concepts have developed, remember they change with time and with shifting societal and political perspectives on mental illness. How we treat people with psychological disorders is partly a function of how society views these people. For example, do people with mental illness need help and protection, or does society need protection from them? As public opinion about people with mental illness changes, so do the relevant laws, and legal and ethical issues affect both research and practice. As you will see, the issues affecting research and practice are often complementary. For example, confidentiality is required to protect the identity of a participant in a research study and of a patient seeking help for a psychological disorder. Because people who receive mental health services often simultaneously participate in research studies, we must consider the concerns of both constituencies.

## Civil Commitment

The legal system exercises significant influence over the mental health system, for better or for worse. Laws have been designed to protect people who display abnormal behavior and to protect society. Often, achieving this protection is a delicate balancing act, with the scales sometimes thought to be tipped in favor of the rights of individuals and at other times in favor of society. For example, each state has **civil commitment laws** that detail when a person can be legally declared to have a mental illness and be placed in a hospital for treatment (Simon & Shuman, 2009). When Arthur's family tried to have him involuntarily committed to a mental health facility, hospital officials decided that because he was not in imminent danger of hurting himself or others he could not be committed against his will. In this case, the laws protected Arthur from involuntary commitment, but they also put him and others at potential risk by not compelling him to get help.

▲ People with mental illness are treated differently in different cultures.

In a now-classic book, La Fond and Durham (1992) argue that two clear trends in mental health law are evident in the recent history of the United States. According to these authors, a "liberal era" from 1960 to 1980 was characterized by a commitment to individual rights and fairness. In contrast, 1980 to the present has been a "neoconservative era," partly in reaction to the liberal reforms of the 1960s and 1970s that focused on majority concerns, including law and order. In the liberal era, the rights of people with mental illness dominated; in the neoconservative era, the rights of people with mental illness have been limited to provide greater protection to society.

Civil commitment laws in the United States date back to the late 19th century. Before this time, almost all people with severe mental illness were cared for by family members or the community or were left to care for themselves. With the development of a large public hospital system devoted to treating such individuals came an alarming trend: involuntary commitment of people for reasons unrelated to mental illness (Simon & Shuman, 2009). There were even instances in which women were committed to psychiatric hospitals by their husbands simply for holding differing personal or political views. In the 1800s, Mrs. E. P. W. Packard crusaded for better civil commitment laws after being involuntarily confined to a psychiatric hospital for 3 years (Grob, 2009).

## Criteria for Civil Commitment

Historically, states have permitted commitment when several conditions have been met: (1) The person has a "mental illness" and is in need of treatment, (2) the person is dangerous to himself or herself or others, or (3) the person is unable to care for himself, a situation considered a "grave disability." How these conditions are interpreted has varied over the years and has always been controversial. It is important to see that the government justifies its right to act against the wishes of an individual—in this case, to commit someone to a mental health facility—under two types of authority: police power and *parens patriae* ("state or country as the parent") power. Under police power, the government takes responsibility for protecting the public health, safety, and welfare and can create laws and regulations to ensure this protection. Criminal offenders are held in custody if they are a threat to society. The state applies *parens patriae* power when citizens are not likely to act in their own best interest, for example, to assume custody of children who have no living parents. Similarly, it is used to commit individuals with severe mental illness to mental health facilities when it is believed that they might be harmed because they are unable to secure the basic necessities of life, such as food and shelter (grave disability), or because they do not recognize their need for treatment (Simon & Shuman, 2008). Under *parens patriae* power, the state acts as a surrogate parent, presumably in the best interests of a person who needs help.

A person in need of help can always voluntarily request admission to a mental health facility; after an evaluation by a mental health professional, a patient may be accepted for treatment. However, when an individual does not voluntarily seek help but others feel that treatment or protection is necessary, the formal process of civil commitment can be initiated. The specifics of this process differ from state to state, but it usually begins with a petition by a relative or mental health professional to a judge. The court may then request an examination to assess psychological status, ability for self-care, need for treatment, and potential for harm. The judge

▲ The government can exert *parens patriae* to protect people from hurting themselves.

considers this information and decides whether commitment is appropriate. This process is similar to other legal proceedings, and the person under question has all the rights and protections provided by the law. In most states, the person can even request that a jury hear the evidence and make a determination. In all cases, the person must be notified that the civil commitment proceedings are taking place, must be present during the trial, must have representation by an attorney, and can examine the witnesses and request an independent evaluation. These safeguards are built into the civil commitment process to guarantee the rights of the person being examined and to ensure that no one is involuntarily committed to a psychiatric facility for other than legitimate reasons.

In emergency situations, when there is clearly immediate danger, a short-term commitment can be made without the formal proceedings required of a civil commitment. Family members or sometimes police officers certify that the person presents a "clear and present danger" to herself or to others (Simon & Shuman, 2009). Arthur's family was unsuccessful in having him admitted on an emergency basis because it was not clear that anyone was in immediate danger, only that someone might be hurt. Again, deciding what is a clear and present danger sometimes requires a great deal of subjective judgment from the court and from mental health professionals.

### *Defining Mental Illness*

The concept of mental illness figures prominently in civil commitment, and it is important to understand how it is defined. **Mental illness** is a legal concept, typically meaning severe emotional or thought disturbances that negatively affect an individual's health and safety. Each state has its own definition. For example, in New York, "'Mental illness' means an affliction with a mental disease or mental condition which is manifested by a disorder or disturbance in behavior, feeling, thinking, or judgment to such an extent that the person afflicted requires care, treatment and rehabilitation" (*New York Mental Hygiene Law,* 1992). In contrast, in Connecticut, "'Mentally ill person' means a person who has a mental or emotional condition that has substantial adverse effects on his or her ability to function and who requires care and treatment, and specifically excludes a person who is an alcohol-dependent person or a drug-dependent person" (Conn. Gen. Stat. Ann., 1992). Many states exclude cognitive disability or substance-related disorders from the definition of mental illness.

Mental illness is *not* synonymous with psychological disorder; in other words, receiving a diagnosis according to the *Diagnostic and Statistical Manual (DSM-IV-TR)* does not necessarily mean that a person's condition fits the legal definition of mental illness. Although the *DSM* is quite specific about criteria that must be met for diagnosis, there is considerable ambiguity about what constitutes a "mental condition" or what are "adverse effects on his or her ability to function." This allows flexibility in making decisions individually, but it also maintains the possibility of subjective impression and bias as influences on these decisions.

### *Dangerousness*

Assessing whether someone is a danger to self or others is a critical determinant of the civil commitment process. **Dangerousness** is a particularly controversial concept to describe people with mental illness: popular opinion tends to be that people who are mentally ill are more dangerous than those who are not. Although this conclusion is questionable, it is still widespread, partly because of sensational media reports. Such views are important to the process of civil commitment if they bias a determination of dangerousness and unfairly link it with severe mental illness.

There is a widespread popular belief that mental illness causes a person to be violent (Kobau, DiIorio, Chapman, & Delvecchio, 2010). The results of research on dangerousness and mental illness are often mixed, but evidence points to a moderately increased rate of violence among people with mental illness (Elbogen & Johnson, 2009). Closer examination of this kind of research reveals that although having a mental illness generally does increase the likelihood of future violence, specific symptoms (such as hallucinations, delusions, or having a comorbid personality disorder) appear to be associated with people at increased risk of violence (Lurigio & Harris, 2009). Even previously violent individuals with mental illness are not necessarily going to commit violent crimes after they are released, although the presence of certain symptoms may increase the risk.

Unfortunately, the widely held misperception that people with mental illness are more dangerous may differentially affect ethnic minorities (Vinkers, de Vries, van Baars, & Mulder, 2010). Black males are often perceived as dangerous, even when they don't exhibit any violent behavior, which may partly explain why blacks are overrepresented among those who are involuntarily committed to state psychiatric institutions (Lindsey, Joe, Muroff, & Ford, 2010).

To return to the general issue, how do you determine whether a person is dangerous to others? How accurate are mental health professionals at predicting who will and who will not later be violent? The answers bear directly on the process of civil commitment, as well as on protection for society. If we can't accurately predict dangerousness, how can we justify involuntary commitment?

Clinicians are better at assessing the relative risk required of the legal system than determining dangerousness case by case (Scott, Quanbeck, & Resnick, 2008). Stated in another way, mental health professionals can identify groups of people who are at greater risk than the general population for being violent—such as having a previous history of both violence and drug or alcohol dependence—and can so advise the court. What clinicians cannot yet do is predict with certainty whether a particular person will or will not become violent.

## Changes Affecting Civil Commitment

Clearly, there are significant problems with the process of civil commitment. In particular, deciding whether a person has a mental illness or is dangerous requires considerable subjective judgment and, because of varying legal language, this determination can differ from state to state. These problems have resulted in a number of significant legal developments. We look next at how changes in civil commitment procedures have resulted in significant economic and social consequences, including an impact on one of our more important social problems: homelessness.

### The Supreme Court and Civil Commitment

In 1957, the parents of Kenneth Donaldson had him committed to the Florida State Hospital for treatment of paranoid schizophrenia. Donaldson was not considered dangerous, yet, despite repeated offers of placement in a halfway house or with a friend, Dr. O'Connor, the superintendent of the hospital, refused to release him for almost 15 years, during which Donaldson received virtually no treatment (Donaldson, 1976). Donaldson successfully sued Dr. O'Connor for damages, winning $48,500. In deciding the case, the Supreme Court found that "a State cannot constitutionally confine . . . a nondangerous individual who is capable of surviving safely in freedom by himself or with the help of willing and responsible family and friends" (*O'Connor v. Donaldson,* 1975).

Here, and in a subsequent decision known as *Addington v. Texas* (1979), the Supreme Court said that more than just a promise of improving quality of life is required to commit someone involuntarily. If nondangerous people can survive in the community with the help of others, they should not be detained against their will. Needing treatment or having a grave disability was not sufficient to commit someone involuntarily with a mental illness. The effect of this decision was to limit substantially the government's ability to commit individuals unless they were dangerous (Simon & Shuman, 2008).

### Criminalization

Because of the tightened restrictions on involuntary commitment that prevailed in the 1960s and 1970s, many people who would normally have been committed to mental health facilities for treatment were instead being handled by the criminal justice system. In other words, people with severe mental illness were now living in the community, but many were not receiving the mental health services they needed and would eventually run afoul of the legal system because of their behavior. This "criminalization" of the mentally ill was of great concern because the criminal justice system was not prepared to care for these individuals (Lamb, 2009; Lamb & Weinberger, 2009). Family members were increasingly frustrated that they couldn't obtain treatment for their loved ones, who were instead languishing in jail without help.

### Deinstitutionalization and Homelessness

In addition to criminalization, two other trends emerged at this time, starting in the 1980s: an increase in the number of people who were homeless and **deinstitutionalization**, the movement of people with severe mental illness out of institutions. Remember that homelessness is not exclusively a problem of the mentally ill. Approximately 2 million to 3 million people will experience a night of homelessness in the United States each year, and estimates place the numbers of homeless people at up to 800,000 on any given night (Hudson & Vissing, 2010). The estimates of psychological disorders among those who are homeless vary, in part because of the difficulty in tracking these individuals. Best estimates suggest that diagnoses of severe mental illness (for example, schizophrenia and bipolar disorder) among homeless persons range from 3% to 42%, depression from 4% to 41% and personality disorders from 3% to 71% (Fazel, Khosla, Doll, & Geddes, 2008). For reasons not yet fully understood, ethnicity may also play a part in who among people with mental illness becomes homeless. In a large study in San Diego County, for example, Latinos and Asian Americans with mental illness were less likely to become homeless, but African Americans were more likely to be homeless (Folsom et al., 2005).

Information on the characteristics of people who are homeless is important because it provides us with clues about why people become homeless, and it dispels the notion that all homeless people have mental health problems. For a time, homelessness was blamed on strict

▲ Larry Hogue was involuntarily committed to a psychiatric hospital because, homeless and under the influence of drugs (left), he terrorized residents of a New York City neighborhood for years. Once off drugs (right), Hogue was able to control himself.

civil commitment criteria and deinstitutionalization (Colp, 2009); that is, policies to severely limit who can be involuntarily committed, the limits placed on the hospital stays of people with severe mental illness, and the concurrent closing of large psychiatric hospitals were held responsible for the substantial increase in homelessness during the 1980s. Although a sizable percentage of homeless people have mental illness, the rise in homelessness is also the result of such economic factors as increased unemployment and a shortage of low-income housing (Wright, 2009). Yet the perception that civil commitment restrictions and deinstitutionalization caused homelessness resulted in movements to change commitment procedures.

Reforms in civil commitment that made it more difficult to commit someone involuntarily occurred at the same time the policy of deinstitutionalization was closing large psychiatric hospitals (Lamb & Weinberger, 2009). Deinstitutionalization had two goals: (1) to close the large state mental hospitals and (2) to create a network of community mental health centers where the released individuals could be treated. Although the first goal appears to have been substantially accomplished, with about a 75% decrease in the number of hospitalized patients (Kiesler & Sibulkin, 1987), the essential goal of providing alternative community care appears not to have been attained. Instead, there was **transinstitutionalization**, or the movement of people with severe mental illness from large psychiatric hospitals to nursing homes or other group residences, including jails and prisons, many of which provide only marginal services (Lamb & Weinberger, 2009). Because of the deterioration in care for many people who had previously been served by the mental hospital system, deinstitutionalization is largely considered a failure. Although many praise the ideal of providing community care for people with severe mental illness, the support needed to provide this type of care has been severely deficient.

### Reactions to Strict Commitment Procedures

Arthur's psychotic reaction and his family's travails in trying to get help occurred during the mid-1970s, a time characterized by greater concern for individual freedom than for society's rights and by the belief that people with mental illness were not properly served by being forced into treatment. Others, however, especially relatives of afflicted people, felt that by not coercing some individuals into treatment, the system was sanctioning their mental decline and placing them at grave risk of harm. The culmination of a number of factors—such as the lack of success with deinstitutionalization, the rise in homelessness, and the criminalization of people with severe mental illness—gave rise to a backlash against their perceived causes, including the strict civil commitment laws. The case of Joyce Brown captures this clash of concerns between individual freedoms for people with mental illness and society's responsibility to treat them.

#### JOYCE BROWN | *Homeless but Not Helpless*

During a 1988 winter emergency in New York City, Mayor Ed Koch ordered that all homeless people who appeared to be mentally ill should be involuntarily committed to a mental health facility for their protection. He used the legal principle of *parens patriae* to justify this action, citing the need to protect these individuals from the cold and from themselves. One of the people who was taken off the streets, 40-year-old Joyce Brown, was picked up against her will and admitted to Bellevue Hospital, where she received a diagnosis of paranoid schizophrenia. She had been homeless for some time, swearing at people as they walked by; at one point, she adopted the name Billie Boggs after a New York television personality with whom she fantasized a relationship. Supported by the New York Civil Liberties Union, Brown contested her commitment and was released after 3 months (Tushnet, 2008).

This case is important because it illustrates the conflicting interests over civil commitment. Brown's family had for some time been concerned about her well-being and had tried unsuccessfully to have her involuntarily committed. Although she had never hurt anyone or tried to commit suicide, they felt that living on the streets of New York City was too hazardous, and they feared for her welfare. City officials expressed concern for Brown and others like her, especially during the dangerously cold winter, although some suspected that this was an excuse to remove people with disturbing behavior from the streets of affluent sections (Kasindorf, 1988). Brown chose not to seek treatment and resisted efforts to place her in alternative settings. At times, she could be quite articulate in making a case for her freedom of choice. Only weeks after she was released from the hospital, she was again living on the streets. Brown was involuntarily committed to a mental health facility again in

▲ People become homeless because of many factors, including economic conditions, mental health status, and drug use.

early 1994 and was released at her insistence a short time later. This continued a pattern that lasted for years (Failer, 2002).

Rulings such as *O'Connor v. Donaldson* and *Addington v. Texas* had argued that mental illness and dangerousness should be criteria for involuntary commitment. However, because of cases like Brown's and concerns about homelessness and criminalization, a movement emerged calling for a return to broader civil procedures that would permit commitment not only of those who showed dangerousness to self or others but also of individuals who were not dangerous but were in need of treatment and of those with grave disability. Groups including the National Alliance on Mental Illness, a coalition of family members of people with mental illness, argued for legal reform to make involuntary commitment easier—an emotional response to the failure to protect and treat people with mental illness. Several states in the late 1970s and early 1980s changed their civil commitment laws in an attempt to address these concerns. For example, the state of Washington revised its laws in 1979 to allow commitment of people who were judged to be in need of treatment, which produced a 91% increase in the number of involuntary commitments in the first year it was in effect (Durham & La Fond, 1985). There was essentially no change in the size of the hospital population at this time, only in the status under which patients were committed (La Fond & Durham, 1992). Whereas people were previously detained because of violence, they were now admitted under *parens patriae* powers; also, whereas most admissions had been voluntary, they were now involuntary. Hospitals began to fill up because of longer stays and repeated admissions and they accepted only involuntary admissions; therefore, the result of easing the procedure for involuntarily committing people with mental illness was only to change the authority under which they were admitted.

The special case of sex offenders has attracted public attention in recent years, and the issue of how to treat repeat offenders is at the heart of the concerns over civil commitment. In the years between 1930 and 1960, some states passed "sexual psychopath laws" that provided hospitalization instead of incarceration, but for an indefinite period (Saleh, Malin, Grudzinskas Jr., & Vitacco, 2010). Sex offenders (rapists and pedophiles) could be civilly committed until they demonstrated that treatment was effective. However, because treatment is often unsuccessful when attempted with uncooperative clients (see Chapter 10) and because public opinion moved from a priority to treat to a priority to punish, these laws were repealed or went unused. Recent efforts have focused on incarcerating sex offenders for their crimes and, if they are judged still dangerous at the end of their sentences, civilly committing them. Such "sexual predator" laws were first enacted in 1990, and the Kansas version was upheld as constitutional by the U.S. Supreme Court (*Kansas v. Hendricks,* 1997). Confinement of this type was viewed by the court as acceptable because it was seen as treatment, even though the justices conceded that such treatment is often ineffective (Zonana & Buchanan, 2009). Some are greatly concerned that these types of laws give the government too much latitude in using civil commitment (as opposed to incarceration) just to keep certain individuals away from others in society (La Fond, 2005).

©J A Giordano/CORBIS SABA

▲ A significant number of the homeless are individuals with mental disorders, many of whom live with their children in shelters or on the streets.

## An Overview of Civil Commitment

What should the criteria be for involuntarily committing someone with severe mental illness to a mental health facility? Should imminent danger to self or others be the only justification, or should society act as a parent and coerce people who appear to be in distress and in need of asylum or safety? How do we address the concerns of families like Arthur's who see their loved ones overcome by psychological problems? And what of our need not to be harassed by people like Brown? When do these rights take precedence over the rights of an individual to be free from unwanted incarceration? It is tempting to conclude that the legal system has failed to address these issues and reacts only to the political whims of the times.

However, from another point of view, the periodic change in laws is a sign of a healthy system that responds to the limitations of previous decisions. The reactions by the Supreme Court in the 1970s to the coercive and arbitrary nature of civil commitment were as understandable as more recent attempts to make it easier to commit people in obvious need of help. As the consequences of these changes become apparent, the system responds to correct injustices. Although improvements may seem excruciatingly slow and may not always correctly address the issues in need of reform, the fact that laws can be changed should make us optimistic that the needs of individuals and of society can ultimately be addressed through the courts.

### Concept Check 16.1

Check your understanding of civil commitment by filling in the blanks.

Several conditions must be met before the state is permitted to commit a person involuntarily: The person has a(n) (1) _____________ and is in need of treatment, the person is considered (2) _____________ to herself or others, and the person is unable to care for himself or herself, also known as (3) _____________.

Mental illness is a(n) (4) _____________ concept, typically meaning severe emotional or thought disturbances that negatively affect an individual's health and safety, although this definition differs from state to state. When the laws about civil commitment emerged, (5) _____________ (movement of disabled individuals out of mental institutions) and (6) _____________ (movement of disabled individuals to a lesser facility) also occurred.

## Criminal Commitment

What would have happened if Arthur had been arrested for trespassing on embassy grounds or, worse yet, if he had hurt or killed someone in his effort to present his plan for saving the world? Would he have been held responsible for his actions, given his obvious disturbed mental state? How would a jury have responded to him when he seemed fine just several days later? If he was not responsible for his behavior then, why does he seem so normal now?

These questions are of enormous importance as we debate whether people should be held responsible for their criminal behavior despite the possible presence of mental illness. Cases such as that of Andrea Yates, who was first convicted and sentenced to life in prison for drowning her five children in a bathtub in 2001 but later found not guilty by reason of insanity (NGRI), causes some to wonder whether the laws have gone too far. **Criminal commitment** is the process by which people are held because (1) they have been accused of committing a crime and are detained in a mental health facility until they can be assessed as fit or unfit to participate in legal proceedings against them or (2) they have been found not guilty of a crime by reason of insanity.

### The Insanity Defense

The purpose of our criminal justice system is to protect our lives, our liberty, and our pursuit of happiness, but not all people are punished for criminal behavior. The law recognizes that, under certain circumstances, people are not responsible for their behavior and it would be unfair and perhaps ineffective to punish them. Current views originate from a case recorded more than 150 years ago in England. Daniel M'Naghten today might receive the diagnosis of paranoid schizophrenia. He held the delusion that the English Tory party was persecuting him, and he set out to kill the British prime minister. He mistook the man's secretary for the prime minister and killed the secretary instead. In what has become known as the M'Naghten rule, the English court decreed that people are not responsible for their criminal behavior if they do not know what they are doing or if they don't know that what they are doing is wrong. This ruling was, in essence, the beginning of the *insanity defense* (see summary in Table 16.1). For more than 100 years, this rule was used to determine culpability when a person's mental state was in question.

In the intervening years, other standards have been introduced to modify the M'Naghten rule because many critics felt that simply relying on an accused person's knowledge of right or wrong was too limiting and a broader definition was needed (Simon & Shuman, 2009). Mental illness alters not only a person's cognitive abilities but also that person's emotional functioning, and mental health professionals believed the entire range of functioning should

**TABLE 16.1** Important Factors in the Evolution of the Insanity Defense

| Factor | Date | Quotation |
|---|---|---|
| M'Naghten rule | 1843 | [I]t must be clearly proved that at the time of committing the act, the party accused was labouring under such a defect of reason, from disease of the mind, as not to know the nature and quality of the act he was doing; or if he did know it, that he did not know he was doing what was wrong. (101 Cl. & F. 200, 8 Eng. Rep. 718, H.L. 1843) |
| Durham rule | 1954 | An accused is not criminally responsible if his unlawful act was the product of mental disease or mental defect. (*Durham v. United States,* 1954) |
| American Law Institute (ALI) rule | 1962 | 1. A person is not responsible for criminal conduct if at the time of such conduct as a result of mental disease or defect he lacks substantial capacity either to appreciate the criminality (wrongfulness) of his conduct or to conform his conduct to the requirements of law.<br>2. As used in the Article, the terms "mental disease or defect" do not include an abnormality manifested only by repeated criminal or otherwise antisocial conduct. (American Law Institute, 1962) |
| Diminished capacity | 1978 | Evidence of abnormal mental condition would be admissible to affect the degree of crime for which an accused could be convicted. Specifically, those offenses requiring intent or knowledge could be reduced to lesser included offenses requiring only reckless or criminal neglect. (New York State Department of Mental Hygiene, 1978) |
| Insanity Defense Reform Act | 1984 | A person charged with a criminal offense should be found not guilty by reason of insanity if it is shown that, as a result of mental disease or mental retardation, he was unable to appreciate the wrongfulness of his conduct at the time of his offense. (American Psychiatric Association, 1983, p. 685) |

*Source:* Reprinted, with permission, from Silver, E., Cirincione, C., & Steadman, H. J. (1994). Demythologizing inaccurate perceptions of the insanity defense. *Law and Human Behavior, 18,* 63–70, © 1994 Plenum Press.

be taken into account when a person's responsibility was determined. One influential decision, known as the Durham rule, was initiated in 1954 by Judge David Bazelon of the Federal Circuit Court of Appeals for the District of Columbia and based on the case *Durham v. United States* (1954). The Durham rule broadened the criteria for responsibility from knowledge of right or wrong to include the presence of a "mental disease or defect" (see Table 16.1). This decision was initially hailed by mental health professionals because it allowed them to present to a judge or jury a complete picture of the person with mental illness. Unfortunately, it was soon apparent that mental health professionals did not have the expertise to assess reliably whether a person's mental illness caused the criminal behavior in question and therefore that decisions were being based on unscientific opinions (Simon & Shuman, 2009). Although the Durham rule is no longer used, it caused a reexamination of the criteria used in the insanity defense.

An influential study of this question was conducted around the same time as the Durham decision by a group of attorneys, judges, and law scholars who belonged to the American Law Institute (ALI). Their challenge was to develop criteria for determining whether a person's mental competence makes him answerable for criminal behavior. The ALI first reaffirmed the importance of distinguishing the behavior of people with mental illness from that of people without mental disorders. Its members pointed out that the threat of punishment was unlikely to deter someone who had severe mental illness; the group's position was that these individuals should instead be treated until they improve and should then be released. (This recommendation is discussed further when we examine recent developments and criticisms of the insanity defense.) The ALI concluded that people are not responsible for their criminal behavior if, because of their mental illness, they cannot recognize the inappropriateness of their behavior or control it (ALI, 1962). The criteria shown in Table 16.1, known as the ALI test, stipulate that a person must either be unable to distinguish right from wrong—as set forth in the M'Naghten rule—or be incapable of self-control to be shielded from legal consequences.

The ALI also included provisions for the concept of **diminished capacity** (see Table 16.1), which holds that people's ability to understand the nature of their behavior and therefore their criminal intent can be diminished by their mental illness. The theory of criminal intent—otherwise called *mens rea,* or having a "guilty mind"—is important legally because to convict someone of a crime, there must be proof of the physical act *(actus rea)* and the mental state *(mens rea)* of the person committing the act (Simon & Shuman, 2009). For example, if a woman accidentally hits someone who steps in front of her car and the person subsequently dies, the woman would not be held criminally responsible; although a person was killed, there was no criminal intent—the driver didn't deliberately hit the person and attempt murder. The diminished capacity concept proposes that a person with mental illness who commits a criminal offense may not, because of the illness, have criminal intent and therefore cannot be held responsible.

## Reactions to the Insanity Defense

Judicial rulings through the 1960s and 1970s regarding criminal responsibility parallel the course of civil commitment. An effort was made to focus on the needs of people with mental illness who also broke the law, providing mental health treatment instead of punishment. However, the successful use of concepts such as *insanity* or *diminished capacity* in criminal cases alarmed large segments of the population. For instance, in 1979 a man successfully pleaded NGRI after being arrested for writing bad checks. His case was based on the testimony of an expert witness who said he suffered from pathological gambling disorder and he therefore could not distinguish right from wrong (*State v. Campanaro,* 1980). Other successful defenses were based on disorders in the *DSM,* such as posttraumatic stress disorder and kleptomania (Novak, 2010), and on disorders not covered in the *DSM,* including battered wife syndrome (Cookson, 2009).

Without question, the case that prompted the strongest outrage against the insanity defense and the most calls for its abolition is that of John W. Hinckley, Jr. (Zapf, Zottoli, & Pirelli, 2009). On March 31, 1981, as President Ronald Reagan walked out of the Washington Hilton Hotel, Hinckley fired several shots, hitting and seriously wounding the president, a Secret Service agent, and James Brady, the president's press secretary. In an instant, Secret Service agents tackled and disarmed Hinckley. Hinckley was obsessed with actress Jodie Foster; he claimed he tried to kill the president to impress her. Hinckley was judged by a jury to be NGRI, using the ALI standard. The verdict sent shock waves throughout the country and legal community (Zapf et al., 2009). One of the many consequences of this event was that James Brady and his wife Sarah became advocates for stricter gun control laws and saw the ultimate passage of the Brady law in 1994.

Although the insanity defense had already been criticized, about 75% of the U.S. states substantially changed their insanity defense rules after Hinckley's verdict, making it more difficult to use this defense (Simon & Shuman, 2008). As you have seen before, such impulses often are based more on emotion than on fact. Highly publicized cases such as those of Hinckley, Charles Manson, Jeffrey Dahmer, and Ted Kaczynski, with the media characterization of people with mental illness as excessively violent, have created an unfavorable public perception of the insanity defense. One telephone survey study found that 91% of people who responded agreed with the statement, "judges and juries have a hard time telling whether the defendants are really sane or insane" (Hans, 1986). Almost 90% agreed the "insanity plea is a loophole that allows too many guilty people to go free." In a similar study, 90% of people agreed "the insanity plea is used too much. Too many people escape responsibilities for crimes by pleading insanity" (Pasewark & Seidenzahl, 1979). Is there hard evidence that the insanity defense is used too often?

▲ James Brady, President Ronald Reagan's press secretary, was wounded in 1981 by a gunman attempting to assassinate the president. In 1994, Brady and his wife Sarah celebrated the passage of the Brady law, which imposed stricter controls on the possession of handguns.

A study of the public's impression of the insanity defense compared it to the actual use of the defense and its outcomes (Silver, Cirincione, & Steadman, 1994). As Table 16.2 shows, the public's perception that this defense is used in 37% of all felony cases is a gross overestimate; the actual figure is less than 1%. The public also overestimates how often the defense is successful, as well as how often people judged NGRI are set free. People tend to underestimate the length of hospitalization of those who are acquitted. This last issue is important: In contrast to public perceptions, the length of time a person is confined to a hospital after being judged NGRI may exceed the time the person would have spent in jail had that person been convicted of the crime (Simon & Shuman, 2008). Hinckley, for example, has been a patient in St. Elizabeth's Hospital for more than 30 years. Other research shows that individuals with mental illness who are found guilty of *nonviolent* crimes can be committed more than 8 times as long as those people without mental illness placed in prison (Perlin, 2000). In contrast to public perception, people with mental illness apparently do not often "beat the rap" as a result of being judged NGRI.

**TABLE 16.2** Comparison of Public Perceptions with the Actual Occurrence of the Insanity Defense

| | Public Perception (%) | Actual Occurrence (%) |
|---|---|---|
| **Use of Insanity Defense** | | |
| Felony indictments resulting in an insanity plea | 37.0 | 0.9 |
| Insanity pleas resulting in acquittal | 44.0 | 26.0 |
| **Disposition of Insanity Acquittees** | | |
| Insanity acquittees sent to a mental hospital | 50.6 | 84.7 |
| Insanity acquittees set free | 25.6 | 15.3 |
| Conditional release | | 11.6 |
| Outpatient | | 2.6 |
| Release | | 1.1 |
| **Length of Confinement of Insanity Acquittees (in months)** | | |
| All crimes | 21.8 | 32.5 |
| Murder | | 76.4 |

*Source:* Reprinted, with permission, from Silver, E., Cirincione, C., & Steadman, H. J. (1994). Demythologizing inaccurate perceptions of the insanity defense. *Law and Human Behavior, 18,* 63–70, © 1994 Plenum Press.

Despite sound evidence that it is not used excessively and does not result in widespread early release of dangerous individuals, major changes were made in the criteria for the insanity defense after the Hinckley verdict. Both the American Psychiatric Association (1983) and the American Bar Association (1984) recommended modifications, moving back toward M'Naghten-like definitions. Shortly afterward, Congress passed the Insanity Defense Reform Act of 1984, which incorporated these suggestions and made successful use of the insanity defense more difficult.

Another attempt at reforming the insanity plea has been to replace the NGRI verdict with a verdict of guilty but mentally ill (GBMI) (Torry & Billick, 2010). Although there are several versions of the GBMI verdict, the shared premise is that the consequences for a person ruled GBMI are different from those for a person who is NGRI. People found to be NGRI are not sent to prison but are evaluated at a psychiatric facility until such time as they are judged ready for release. A person determined to be no longer mentally ill must be released. If Arthur had committed a crime and was found NGRI, because his brief psychotic disorder was quickly resolved, he would probably have been released immediately. In contrast, one version of the GBMI verdict in theory allows the system both to treat and to punish the individual. The person found guilty is given a prison term just as if there were no question of mental illness. Whether the person is incarcerated in prison or in a mental health facility is decided by legal authorities. If the person recovers from mental illness before the sentence has passed, that person can be confined in prison for the maximum length of the term. If Arthur were found GBMI under this system, he could serve a full prison sentence, even though his mental illness was resolved. This version of GBMI has been adopted by a number of states (Simon & Shuman, 2008).

▲ Theodore Kaczynski, once a promising mathematician (left), became a notorious terrorist who killed 3 people and injured 23 more with handmade bombs sent through the mail. Awaiting trial as the Unabomber (right), Kaczynski refused to cooperate with his lawyers, who fought to have him declared mentally ill to save his life. Ironically, the prosecution, in pressing for the death penalty, supported his claim of sanity. (In the end, Kaczynski pleaded guilty and accepted a life sentence.)

The second version of GBMI is even harsher for the mentally ill offender. Convicted individuals are imprisoned, and prison authorities may provide mental health services if they are available. The verdict itself is simply a declaration by the jury that the person was mentally ill at the time the crime was committed and does not result in differential treatment for the perpetrator. Idaho, Montana, and Utah have abandoned the insanity defense altogether and have adopted this version of GBMI ("The Evolving Insanity Defense," 2006).

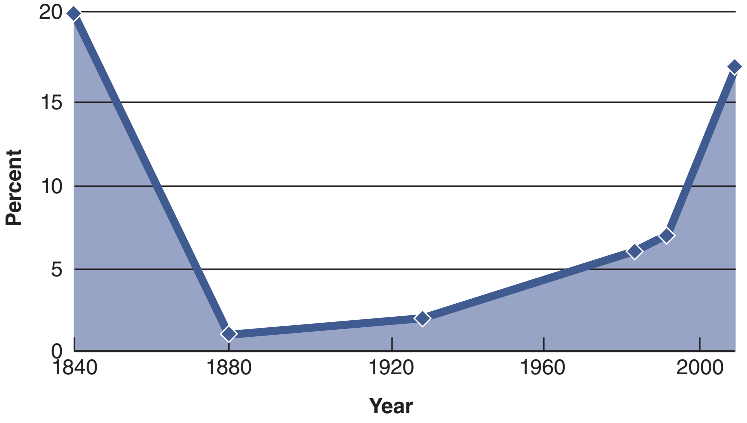
As noted, the GBMI verdict was a reaction to the perceived loophole provided by the insanity defense. It has been used in several states for more than 15 years, and its effects have been investigated by researchers. Two studies have shown that people who receive the GBMI verdict are more likely to be imprisoned and to receive longer sentences than people pleading NGRI (Callahan, McGreevy, Cirincione, & Steadman, 1992; Keilitz, 1987). Research also indicates that individuals receiving GBMI verdicts are no more likely to receive treatment than other prisoners who have mental illness (Keilitz, 1987; Smith & Hall, 1982). Currently, the type of verdicts available (NGRI versus GBMI) depends on the laws of the particular state where the crimes were committed. Overall, some estimate that there are more than 3 times the number of people with severe mental illness in jails than in hospitals, pointing to the consequences of these changes in mental health laws (Torrey, Eslinger, Lamb, & Pavle, 2010). ■ Figure 16.1 illustrates how people with severe mental illness are increasingly being placed in prisons rather than in special mental health facilities. The percentage of placements in prisons is approaching rates comparable to that of those more than 150 years ago, before adequate services were available.

## Therapeutic Jurisprudence

There is a built-in tension between the judicial system and the mental health system. The legal system is, by design, adversarial. In other words, it was created with prosecutors and defendants, winners and losers. In contrast, the mental health system is set up to find solutions to important psychological problems without placing blame on any parties. The goal is for both sides to "win." Fortunately, there is an increasing recognition in the legal system that a strict adversarial approach to dealing with people with mental health problems may be harmful to everyone. As a result of this change in thinking, when individuals with psychological disorders break the law, they may now find themselves in one of a variety of "problem-solving courts" (King & Wexler, 2010). These new courts are designed to address the unique needs of people with specific problems. For example, today in many states you can find drug treatment courts, domestic violence courts, and mental health courts, among others. Interestingly, models of problem-solving courts have their roots in the legal systems of tribal societies in the United States, Canada, Australia, and New Zealand (King & Wexler, 2010).

These problem-solving courts are based on the concept of therapeutic jurisprudence—in essence, using what we know about behavior change to help people in trouble with the law. In drug treatment court, for example, a judge might be assigned to all criminal cases involving drug-addicted defendants. The judge would have the leeway to delay sentencing under the condition that the accused obtained and held a job for 6 months, received drug treatment during that time, and remained drug free. Similarly, a defendant in a mental health court might be helped by referrals to existing programs in the community and involvement of family members. Rather than simply trying to decide between prison and freedom, the court can serve as an instrument of social change. This evolving concept may provide effective alternatives in the criminal justice system for people with severe mental illness.

Society has long recognized the need to identify criminals who may not be in control of their behavior and who may not benefit from simple incarceration. The challenge is in trying to do what may be impossible: determining whether the person knew what she was doing, knew right from wrong, and could control her behavior. Mental health professionals cannot assess mental health retrospectively. An additional dilemma is the desire, on the one hand, to provide care to people with mental illness and, on the other, to treat them as responsible individuals. Finally, we must resolve the simultaneous and conflicting interests of wanting to assist people with mental illness and wanting to be protected from them. The recent trend of using problem-solving courts may be one way to address these concerns. We must reach a national consensus about the basic value of people with mental illness to decide how they should be dealt with legally. We hope the recent trend of favoring law and order over the rights of people with mental illness can be moderated to provide attention to both concerns.



■ **FIGURE 16.1** The percentage of jail and prison inmates with serious mental illness. The graph shows the increasing trend over the past few decades to incarcerate people with severe mental illness rather than to provide treatment. From Torrey, E., Eslinger, S., Lamb, R., & Pavle, J. (2010). *More mentally ill persons are in jails and prisons than hospitals: A survey of the states* (p. 13). Arlington, VA: Treatment Advocacy Center.

## Competence to Stand Trial

Before people can be tried for a criminal offense, they must be able to understand the charges against them and to assist with their own defense, criteria outlined by the Supreme Court in *Dusky v. United States* (1960). Thus, in addition to interpreting a person's state of mind during the criminal act, experts must also anticipate his state of mind during the subsequent legal proceedings. A person could be ruled

NGRI because of his mental illness at the time of the criminal act yet still be competent to stand trial, a situation that would have occurred in Arthur's case had he committed a crime.

A person determined to be incompetent to stand trial typically loses the authority to make decisions and faces commitment. Because a trial requires a determination of **competence**, most people with obvious and severe impairments who commit crimes are never tried. Some observers estimate that for every person who receives a verdict of NGRI, 45 others are committed to a mental health facility with a diagnosis of severe mental illness (Butler, 2006). The length of stay is the time it takes the committed person to regain competence. Because this period can be drawn out, the courts have ruled it cannot be indefinite and that, after a reasonable amount of time, the person must be found competent, set free, or committed under civil law (*Jackson v. Indiana,* 1972). Laws are often not precise in their language, and the phrase "reasonable amount of time" is open to a great deal of interpretation.

A final issue relates to the legal concept of burden of proof, the weight of evidence needed to win a case. In decisions of competence to stand trial, an important ruling placed responsibility on the defendant to provide the burden of proof—in this case, that she is incompetent to stand trial (*Medina v. California,* 1992). Again, public concern that dangerous individuals with mental illness are routinely acquitted and let loose on society after committing multiple violent offenses flies in the face of the facts. More realistically, a person with mental illness commits a nonviolent crime and receives treatment through legal actions, such as the competence proceedings.

## Duty to Warn

Do mental health professionals have any responsibility for the actions of the people they serve? This is especially important when we consider the dangerous behavior exhibited by a minority of people with severe mental illness. What are the responsibilities of professionals who suspect that someone with whom they are working may hurt or even kill another person? Must they contact the appropriate authority or the person who may be harmed, or are they forbidden to discuss information disclosed during therapy sessions?

These issues were the subject of a tragic case known as *Tarasoff v. Regents of the University of California* (1974, 1976). In 1969, Prosenjit Poddar, a graduate student at the University of California, killed a fellow student, Tatiana Tarasoff, who had previously rejected his romantic advances. At the time of the murder, he was being seen by two therapists at the University Health Center and had received a diagnosis of paranoid schizophrenia. At his last session, Poddar hinted that he was going to kill Tarasoff. His therapist believed this threat was serious and contacted the campus police, who investigated the allegation and received assurances from Poddar that he would leave Tarasoff alone. Weeks later, after repeated attempts to contact her, Poddar shot and stabbed Tarasoff until she died.

After learning of the therapists' role in the case, Tarasoff's family sued the university, the therapists, and the university police, saying they should have warned Tarasoff that she was in danger. The court agreed, and the Tarasoff case has been used ever since as a standard for therapists concerning their **duty to warn** a client's potential victims. Related cases have further defined the role of the therapist in warning others (Masona, Worsleyb, & Coylea, 2010). Courts have generally ruled that the threats must be specific. In *Thompson v. County of Alameda* (1980), the California Supreme Court ruled that a therapist does not have a duty to warn when a person makes nonspecific threats against nonspecific people. It is difficult for therapists to know their exact responsibilities for protecting third parties from their clients. Good clinical practice dictates that any time they are in doubt they should consult with colleagues. A second opinion can be just as helpful to a therapist as to a client.

## Mental Health Professionals as Expert Witnesses

Judges and juries often have to rely on **expert witnesses**, individuals who have specialized knowledge, to assist them in making decisions (Mullen, 2010). We have alluded to several in-

### Innovative Approaches

### Brain Blame

Throughout this book, we were privileged to chronicle advances in the variety of sciences that contribute to our understanding of abnormal behavior. The integration of these sciences are just now revealing mysteries that only a few years ago were assumed to be out of the reach of our ability to explore why people behave the way they do. As has been true throughout history, however, advancing technology often outpaces society's ability to incorporate this new knowledge in its social and ethical structure.

Take, for example, new research on moral decision making (Rangel, Camerer, & Montague, 2008). Research using functional imaging technologies reveals that our ability to "feel the pain" of other people—feeling empathetic to others in distress—involves activation of the prefrontal cortex (Robertson et al., 2007) and damage to this area prevents people from using empathy to make moral decisions (Damasio, 2007). This important research is now being used in court proceedings to help decide guilt or innocence (Mobbs, Lau, Jones, & Frith, 2009). Will it be argued that defendants who have psychopathy (see Chapter 12), for example, should be judged not responsible for their behavior because their inability to empathize with others has its origin in the brain? This "brain blame" will become more prominent in coming years because our definitions of insanity have not kept up with our understanding of the combined contributions of the environment and biology to mental illness and criminal behavior.

stances in which mental health professionals serve in such a capacity, providing information about a person's dangerousness or ability to understand and participate in the defense. The public's perception of expert witnesses is characterized by ambivalence. On one hand, they see the value of persuasive expert testimony in educating a jury; on the other, they see expert witnesses as "hired guns" whose opinions suit the side that pays their bills (Simon & Shuman, 2009). How reliable are the judgments of mental health professionals who act as expert witnesses?

To take one example, in deciding whether someone should be civilly committed, the assessor must determine the person's potential for future violence. Research suggests that mental health professionals can make reliable predictions of dangerousness over the short term, for 2 to 20 days after the evaluation (Scott et al., 2008). However, they have not been able to make reliable predictions of violence after longer periods (Tardiff, 2003). A second area in which mental health professionals are often asked to provide consultation is in assigning a diagnosis. In Chapter 3, we discussed the development of systems to ensure the reliability of diagnoses. Recent revisions of diagnostic criteria, most notably *DSM-III-R* and the current *DSM-IV-TR,* have addressed this issue directly, thus helping clinicians make diagnoses that are generally reliable. Remember, however, that the legal definition of mental illness is not matched by a comparable disorder in *DSM-IV-TR.* Therefore, statements about whether someone has a "mental illness" reflect determinations made by the court, not by mental health professionals.

▲ Elizabeth Loftus, a psychologist at the University of Washington in Seattle and an expert in human memory, testifies during the pretrial hearing of former White House official Lewis "Scooter" Libby.

Mental health professionals appear to have expertise in identifying *malingering* and in assessing competence. Remember that to malinger is to fake or grossly exaggerate symptoms, usually to be absolved from blame. For example, a person might claim to have been actively hallucinating at the time of the crime and therefore not responsible. Research indicates that the Minnesota Multiphasic Personality Inventory test is extremely accurate in revealing malingering in people claiming to have serious mental illness. The examiners look for true symptoms, but ones people with mental illness rarely report. Malingerers, in their rush to fake their illness, will often overreport these problems, perhaps to convince others they are mentally ill (Gassen, Pietz, Spray, & Denney, 2007). Mental health professionals also appear capable of providing reliable information about a person's competence, or ability to understand and assist with a defense (Shulman, Cohen, Kirsh, Hull, & Champine, 2007). Overall, mental health professionals can provide judges and juries with reliable and useful information in certain areas (Scott et al., 2008).

The research described here does not indicate how accurate expert testimony is under everyday conditions. In other words, under the right circumstances, experts can make accurate determinations of the short-term risks that a person will commit an act of violence, is faking certain symptoms, or is competent to stand trial and of what diagnosis should be made. Still, other factors conspire to influence expert testimony. Personal and professional opinions that exceed the competence of the expert witness can influence what information is or is not presented, as well as how it is relayed to the court (Simon & Shuman, 2009). For instance, if the expert witness believes generally that people should not be involuntarily committed to mental health facilities, this opinion will likely influence how the witness presents clinical information in civil commitment court proceedings.

## Concept Check 16.2

Check your understanding of criminal commitment by identifying the following concepts: (a) competence to stand trial, (b) diminished capacity, (c) American Law Institute rule, (d) Durham rule, (e) M'Naghten rule, (f) malingering, (g) expert witness, and (h) duty to warn.

1. The defendant does not go to trial because she is unable to understand the proceedings and assist in the defense. ____________
2. The person could not distinguish between right and wrong at the time of the crime. ____________
3. The person is not responsible for the crime if he is not able to appreciate the wrongfulness of behavior caused by mental disease or defect. ____________
4. One of my clients threatened his mother's life during his session today. Now I must decide whether I have a(n) ____________.
5. A mental disorder could lessen a person's ability to understand criminal behavior and to form criminal intent. ____________

6. Dr. Z testified in court that the defendant was faking and exaggerating symptoms to evade responsibility. Dr. Z is acting as a(n) ____________, and the defendant is ____________.
7. The person is not criminally responsible if the crime was the result of "mental disease or mental defect." ____________

## Patients' Rights and Clinical Practice Guidelines

Until about 30 years ago, people in mental health facilities were accorded few rights. What treatment they received and whether they could make phone calls, send and receive mail, or have visitors were typically decided by hospital personnel who rarely consulted with the patient. However, abuses of this authority led to legal action and subsequent rulings by the courts concerning the rights of people in these facilities.

### The Right to Treatment

One of the most fundamental rights of people in mental health facilities is the right to treatment. For too many and for too long, conditions were poor and treatment was lacking in numerous large mental health facilities. Starting in the early 1970s, a series of class-action lawsuits (filed on behalf of many individuals) helped establish the rights of people with mental illness and mental retardation. A landmark case, *Wyatt v. Stickney* (1972), grew out of a lawsuit filed by the employees of large institutions in Alabama who were fired because of funding difficulties and established for the first time the minimum standards that facilities had to meet in relation to the people who were hospitalized. Among the standards set by *Wyatt v. Stickney* were minimum staff–patient ratios and physical requirements, such as a certain number of showers and toilets for a given number of residents. The case also mandated that facilities make positive efforts to attain treatment goals for their patients.

*Wyatt v. Stickney* went further and expanded on a concept called the "least restrictive alternative," indicating that, wherever possible, people should be provided with care and treatment in the least confining and limiting environment possible. For example, the court noted the following for those with mental retardation:

> Residents shall have a right to the least restrictive conditions necessary to achieve the purpose of habilitation. To this end the institution shall make every attempt to move residents from (1) more to less structured living; (2) large to smaller facilities; (3) large to smaller living units; (4) group to individual residences; (5) segregated from the community to integrated into the community; (6) dependent living to independent living. (*Wyatt v. Stickney*, 1972)

Despite this movement to secure treatment for people in mental health facilities, a gap was left as to what constituted proper treatment. The case of *Youngberg v. Romeo* (1982) reaffirmed the need to treat people in nonrestrictive settings but essentially left to professionals the decision about the type of treatment to be provided. This concerned patient advocates because, historically, leaving treatment to professional judgment has not always resulted in the intended end for the people in need of help. In 1986, Congress provided a number of safeguards by passage of the Protection and Advocacy for Mentally Ill Individuals Act (Woodside & Legg, 1990), which established a series of protection and advocacy agencies in each state to investigate allegations of abuse and neglect and to act as legal advocates. This layer of protection has resulted in a balance between professional concerns and needs and rights of patients in mental health facilities.

### The Right to Refuse Treatment

One of the most controversial issues in mental health today is the right of people, especially those with severe mental illness, to refuse treatment (Simon & Shuman, 2009). In recent times, the argument has centered on the use of antipsychotic medications. On one side of the issue are the mental health professionals who believe that, under certain circumstances, people with severe mental illness are not capable of making a decision in their own best interest and that the clinician is therefore responsible for providing treatment, despite the protestations of the affected people. On the other side, patients and their advocates argue that all people have a fundamental right to make decisions about their own treatment, even if doing so is not in their own best medical interests.

Although this controversy is not yet resolved, one court case has responded to a related question: Can people be "forced" to become competent to stand trial? This is an interesting dilemma: If people facing criminal charges are delusional or have such frequent severe hallucinations that they cannot fully participate in the legal proceedings, can they be forced against their will to take medication to reduce these symptoms, thereby making them competent to stand trial? A Supreme Court ruling, *Riggins v. Nevada* (1992), stated that, because of the potential for negative side effects (such as the involuntary motor movements associated with tardive dyskinesia), people cannot be forced to take antipsychotic medication. Although this decision does not settle the issue of refusing treatment, it does indicate the high court's wish to honor individual choice (Simon & Shuman, 2008).

### Research Participants' Rights

Throughout this text we have described research conducted worldwide with people who have psychological disorders. We also touched briefly in Chapter 4 on the issue of the rights of these individuals. In general, people who participate in psychological research have the following rights (American Psychological Association, 2010a, 2010b):

1. The right to be informed about the purpose of the research study
2. The right to privacy
3. The right to be treated with respect and dignity
4. The right to be protected from physical and mental harm
5. The right to choose to participate or to refuse to participate without prejudice or reprisals
6. The right to anonymity in the reporting of results
7. The right to the safeguarding of their records

These rights are particularly important for people with psychological disorders who may not be able to understand them fully. One of the most important concepts in research is that those who participate must be fully informed about the risks and benefits of the study. Simple consent is not sufficient; it must be *informed consent,* or formal agreement by the subject to participate after being fully apprised of all important aspects of the study, including any possibility of harm. An important case underlines the significance of informed consent and the sometimes-gray areas that exist in applied research.

### **GREG ALLER** | *Concerned About Rights*

In 1988, 23-year-old Greg Aller signed a consent form agreeing to participate in a treatment study at the University of California at Los Angeles (UCLA) Neuropsychiatric Institute (Willwerth, 1993). Since the previous year, Greg had experienced vivid and frightening hallucinations and delusions about space aliens. His parents had contacted UCLA for assistance. They learned that the university was initiating a new study to evaluate people in the early stages of schizophrenia and to assess the effects of the withdrawal of medication. If Greg participated, he could receive extremely expensive drug therapy and counseling free. After taking the drug Prolixin for 3 months as part of the study, he improved dramatically; the hallucinations and delusions were gone. He was now able to enroll in college, and he made the dean's list.

Although overjoyed with the results, Greg's parents were concerned about the second phase of the study, which involved taking him off the medication. They were reassured by the researchers that this was an important and normal part of treatment for people with schizophrenia and that the potential for negative side effects of taking the drug for too long was great. They were also told the researchers would put Greg back on the medication if he grew considerably worse without it.

Toward the end of 1989, Greg was slowly taken off the drug, and he soon started having delusions about then-President Ronald Reagan and space aliens. Although his deterioration was obvious to his parents, Greg did not indicate to the researchers that he needed the medication or tell them of his now-continuous hallucinations and delusions. Greg continued to deteriorate, at one point threatening to kill his parents. After several more months, Greg's parents persuaded him to ask for more medication. Although better than he was earlier, Greg has still not returned to the much-improved state he achieved following his first round of medication.

This case highlights the conflicts that can arise when researchers attempt to study important questions in psychopathology. Administrators at the National Institutes of Health reported that the UCLA researchers did not give Greg and his family all the information about the risks of treatment and the possibility of other approaches (Aller & Aller, 1997). Critics claim that informed consent in this and similar situations is too often not fully met and that information is often colored to ensure participation. However, the UCLA researchers note that what they did was no different from what would have happened outside the research study: They attempted to remove Greg from potentially dangerous antipsychotic medication. The controversy emerging from this case should be an added warning to researchers about their responsibilities to people who participate in their studies and their obligation to design added safeguards to protect the welfare of their study subjects. Some are now exploring methods to assess formally whether participants with mental illness fully understand the risks and benefits associated with these studies (e.g., Jeste et al., 2009).

©Mojgan B. Azimi

▲ Greg Aller (right, with his parents) participated in a drug study at UCLA and suffered a severe relapse of psychotic symptoms when medication was withdrawn. He and his family subsequently raised the issue of informed consent for such research.

## Evidence-Based Practice and Clinical Practice Guidelines

Health-care delivery systems around the world have become extremely interested in determining whether treatments commonly used for both physical and psychological disorders are effective. This concern stems partly from the greatly increased expense of health care and from the fact that much of the cost is picked up by governments around the world. As a result, governments and health-care policy makers are increasingly promoting evidence-based practice (EBP)—health-care practices supported by research findings demonstrating that they are effective. EBP is one of those ideas that comes along occasionally and takes the world by storm. Although some tenets of EBP have been around for decades, it is only in the past 15 years that EBP has been formally identified as a systematic method of delivering clinical care (Institute of Medicine, 2001; Sackett, Strauss, Richardson, Rosenberg, & Haynes, 2000). In the United States, the President's New Freedom Commission on Mental Health (2003, p. 21) made the principal recommendation of its final report to advance EBPs and "expand the workforce providing evidence-based mental health services and supports." The American Psychological Association Presidential Task Force in 2006 adopted as policy a report describing EBP in psychology and encouraging wide adoption of the notion of basing principles of psychological practice on evidence (APA, 2006).

As described throughout this book, evidence has accumulated on the effectiveness of psychological treatments for specific disorders both in research clinics and in clinics that serve the public directly. When this evidence is put in the form of recommendations on how to treat a particular problem, these recommendations are called clinical practice guidelines. In 1989, legislation established a new branch of the federal government called the Agency for Health Care Policy and Research. In 1999, this agency was reauthorized by Congress and renamed the Agency for Healthcare Research and Quality. The purpose of this agency is to establish uniformity in the delivery of effective health and mental health care and to communicate to practitioners, policy makers, and patients alike throughout the country the latest developments in treating certain disorders effectively. The agency is also responsible for research into improving systems for the delivery of health and mental health services. Now with the passage in 2010 of legislation to provide a form of national health insurance in the United States (the Patient Protection and Affordable Care Act), making health care more efficient and effective is more important than ever.

The government hopes not only to reduce costs by eliminating unnecessary or ineffective treatments but also to facilitate the utilization of effective interventions based on the latest research evidence. In recent years, governments have allocated billions of dollars to facilitate dissemination and implementation of evidence-based psychological treatments in various health-care systems such as the Veterans Health Administration in the United States and the National Health Service in the United Kingdom (McHugh & Barlow, 2010). Treating people effectively—alleviating their pain and distress—is the most important way to reduce health-care costs because these individuals will no longer request one treatment after another in an unending search for relief. To this end, the new legislation creates the Patient-Centered Outcomes Research Institute to facilitate research on which treatments for what conditions are most effective, and to disseminate this information widely (Dickersin, 2010).

Anticipating the importance of this trend and the necessity that clinical practice guidelines be sound and valid, a task force of the American Psychological Association composed a template, or set, of principles for constructing and evaluating guidelines for clinical interventions for both psychological disorders and psychosocial aspects of physical disorders. These principles were published in 1995 and revised in 2002 with relatively few changes (American Psychological Association, 2002).

The task force decided that clinical practice guidelines for specific disorders should be constructed on the basis of two simultaneous considerations, or axes: the clinical efficacy axis and the clinical utility axis. The **clinical efficacy axis** is a thorough consideration of the scientific evidence to determine whether the intervention in question is effective. This evidence would answer the question, Is the treatment effective when compared to an alternative treatment or to no treatment in a controlled clinical research context? In Chapter 4, we reviewed the various research strategies used to determine whether an intervention is effective.

As you will remember, for many reasons, a treatment might seem effective when it is not. For instance, if patients improve on their own while being treated simply because of the passage of time or the natural healing process, the treatment had little to do with the improvement. It is possible that nonspecific effects of the treatment—perhaps just meeting with a caring health professional—are enough to make someone feel better without any contribution from the particular treatment technique. To determine clinical efficacy, experiments called clinical trials must establish whether the intervention in question is better than no therapy, better than a nonspecific therapy, or better than an alternative therapy. (The latter finding provides the highest level of evidence for a treatment's effectiveness.) Clinicians might also rely on information collected from various clinics where a large number of practitioners are treating the disorder in question. If these clinicians collect systematic data on the outcomes of their patients, they can ascertain how many are "cured," how many improve somewhat without recovering, and how many fail to respond to the intervention. Such data are referred to as *quantified clinical observations* or *clinical replication series.* Finally, a *clinical consensus* of leading experts is also a valuable source of information, although not as valuable as data from quantified clinical observations or randomized controlled trials (in which individuals are assigned randomly to a treatment or a control condition to evaluate the efficacy of the treatment).

The **clinical utility axis** is concerned with the effectiveness of the intervention in the practice setting in which it is to be applied, regardless of research evidence on its efficacy; in other words, will an intervention with proven efficacy in a research setting also be effective in the various clinical settings where the interventions are most often applied? Also, is application of the intervention in the settings where it is needed feasible and cost-effective? This axis is concerned with external validity, the extent to which an internally valid intervention is effective in different settings or under different circumstances from those where it was tested, and how easily it can be disseminated and implemented in those settings.

The first major issue to consider on the clinical utility axis is feasibility. Will patients accept the intervention and comply with its requirements, and is it relatively easy to administer? As noted in Chapter 7, electroconvulsive therapy is an effective treatment for severe depression in many cases, but it is extremely frightening to patients, many of whom refuse it. The treatment also requires sophisticated procedures and close supervision by medical personnel, usually in a hospital setting. Therefore, it is not particularly feasible and is used only as a last resort.

A second issue on the clinical utility axis is generalizability, which refers to the extent to which an intervention is effective with patients of differing backgrounds (ethnicity, age, or sex), as well as in different settings (inpatient, outpatient, or community) or with different therapists. Again, an intervention could be effective in a research setting with one group of patients but generalize poorly across different ethnic groups. In summary, a treatment can be highly effective as determined by the clinical efficacy axis, but unless the treatment is widely generalizable, feasible, and cost-effective, it is unlikely to be disseminated or implemented. For a summary of these two axes, see Table 16.3.

In reading the disorder chapters (Chapters 5–15 of this book), you will have noted a number of effective treatments, both psychosocial and medical. In the future, we will see a great deal of additional research to establish both the clinical efficacy and the clinical utility of various interventions for psychological disorders, and the development of ever more sophisticated clinical practice guidelines. In 2010, the American Psychological Association decided to develop its own set of clinical practice guidelines on providing the best evidence-based psychological care for people with psychological disorders.

In Chapter 1, we reviewed various activities that make up the role of scientist-practitioners in the mental health professions,

**TABLE 16.3** Overview of Template for Constructing Psychological Intervention Guidelines

**Clinical Efficacy (Internal Validity)**

A. Better than alternative therapy (randomized controlled trials, or RCTs)
B. Better than nonspecific therapy (RCTs)
C. Better than no therapy (RCTs)
D. Quantified clinical observations
E. Clinical consensus
  1. Strongly positive
  2. Mixed
  3. Strongly negative
6. Contradictory evidence

**Clinical Utility (External Validity)**

A. Feasibility
  1. Patient acceptability (cost, pain, duration, side effects, and so on)
  2. Patient choice in face of relatively equal efficacy
  3. Probability of compliance
  4. Ease of dissemination (number of practitioners with competence, requirements for training, opportunities for training, need for costly technologies or additional support personnel, and so on)
B. Generalizability
  1. Patient characteristics
    a. Cultural background issues
    b. Gender issues
    c. Developmental level issues
    d. Other relevant patient characteristics
  2. Therapist characteristics
  3. Issues of robustness when applied in practice settings with different time frames, and so on
  4. Contextual factors regarding setting in which treatment is delivered
C. Costs and benefits
  1. Costs of delivering intervention to individual and society
  2. Costs to individual and society of withholding intervention

*Note:* Confidence in treatment efficacy is based on both (a) absolute and relative efficacy of treatment and (b) quality and replicability of studies in which this judgment is made.

*Note:* Confidence in clinical utility as reflected on these three dimensions should be based on systematic and objective methods and strategies for assessing these characteristics of treatment as they are applied in actual practice. In some cases, randomized controlled trials will exist. More often, data will be in the form of quantified clinical observations (clinical replication series) or other strategies, such as health economic calculations.

who take a scientific approach to their clinical work to provide the most effective assessment procedures and interventions. Changes in the delivery of mental health services are likely to be accompanied by considerable disruption, because this is a major system that affects millions of people. But the change will also bring opportunities. Scientist-practitioners will contribute to the process of guidelines development in several ways. For example, as attempts are made to assess the clinical utility or external validity of interventions, the collected experience of thousands of mental health professionals will be immensely valuable. Most information relevant to clinical utility or external validity will be collected by these clinicians in the course of their practice. Thus, they will truly fulfill the scientist-practitioner role to the benefit of patients being treated for mental health issues.

## Conclusions

Therapy and scientific progress do not occur in a vacuum. People who study and treat abnormal behavior are responsible not only for mastering the wealth of information we have only touched on in this book but also for understanding and appreciating their role in society and in the world. Every facet of life—from the biological to the social, political, and legal—interacts with every other facet; if we are to help people, we must appreciate this complexity.

We hope we have given you a good sense of the challenges faced by workers in the field of mental health and have spurred some of you to join us in this rewarding work.

### Concept Check 16.3

Identify the following situation using one of these terms: (a) informed consent, (b) refuse treatment, (c) clinical utility, (d) clinical efficacy, and (e) reduce costs.

1. Recently, clinical practice guidelines were established on two axes. The ____________ axis is a consideration of the scientific evidence to determine whether the intervention in question is effective.
2. The ____________ axis is concerned with an intervention's effectiveness in the clinical setting where it will be applied, not in the research setting.
3. The clinical researcher knows the potential for harm of the participants is slight but is nevertheless careful to tell them about it and asks them whether they agree to give their ____________.
4. Clinical practice guidelines are designed to safeguard clients and ____________.
5. The Supreme Court ruling in *Riggins v. Nevada* helped support a patient's right to ____________.

# Summary

### Perspectives on Mental Health Law

- Societal views of people with mental illness change with time, often as responses to perceived problems with and as intended improvements of relevant laws. According to researchers, a "liberal era" between 1960 and 1980 in the United States was characterized by a commitment to individual rights and fairness; the "neoconservative era" that followed focuses on majority concerns and on law and order.

### Civil Commitment

- Civil commitment laws determine the conditions under which a person may be certified legally to have a mental illness and therefore to be placed in a hospital, sometimes in conflict with the person's own wishes.
- Historically, states have permitted commitment when several conditions have been met: (1) the person has a mental illness and is in need of treatment, (2) the person is dangerous to himself or to others, or (3) the person is unable to care for himself.
- *Mental illness* as used in legal system language is not synonymous with *psychological disorder;* each state has its own definition of mental illness, usually meant to include people with severe disturbances that negatively affect their health and safety.
- Having a mental illness does not seem to increase the likelihood of dangerousness, that is, that a person will commit violent acts in the future, although having symptoms of hallucinations and delusions does seem to indicate more risk for behaving violently.
- The combination of the lack of success with deinstitutionalization, which has resulted instead in transinstitutionalization; the rise in homelessness; and the criminalization of people with severe mental illness led to a backlash against the perceived causes of these factors, including the strict civil commitment laws.

### Criminal Commitment

- Criminal commitment is the process by which people are held for one of two reasons: (1) They have been accused of committing a crime and are detained in a mental health facility until they can be determined fit or unfit to participate in legal proceedings against them, or (2) they have been found not guilty of a crime by reason of insanity.
- The insanity defense is defined by a number of legal rulings: The M'Naghten rule states that people are not responsible for criminal behavior if they do not know what they are doing, or if they do know and they don't know it is wrong. The Durham rule broadened the criteria for responsibility from knowledge of right or wrong to the presence of a "mental disease or defect." The American Law Institute criteria concluded that people were not responsible for their criminal behavior if, because of their mental illness, they lacked either the cognitive ability to recognize the inappropriateness of their behavior or the ability to control their behavior.
- The concept of diminished capacity holds that people's ability to understand the nature of their behavior and therefore their criminal intent could be lessened by their mental illness.
- A determination of competence must be made before an individual can be tried for a criminal offense: To stand trial, people must be competent—able to understand the charges against them and to assist with their own defense.
- Duty to warn is a standard that sets forth the responsibility of the therapist to warn potential victims that a client may attempt to hurt or kill them.
- Individuals who have specialized knowledge and who assist judges and juries in making decisions, especially about such issues as competence and malingering, are called expert witnesses.

### Patients' Rights and Clinical Practice Guidelines

- One of the more fundamental rights of patients in mental health facilities is their right to treatment; that is, they have a legal right to some sort of ongoing effort to both define and strive toward treatment goals. By contrast, a great deal of controversy exists over whether all patients are capable of making a decision to refuse treatment. This is an especially difficult dilemma in the case of antipsychotic medications that may improve patients' symptoms but bring with them severe negative side effects.
- Subjects who participate in any research study must be fully informed of the risks and benefits and formally give their informed consent to indicate they have been fully informed.
- Clinical practice guidelines can play a major role in providing information about types of interventions that are likely to be effective for a specific disorder, thereby setting the stage for evidence-based practice. Critical to such a determination are measures of clinical efficacy (internal validity) and clinical utility (external validity); in other words, the former is a measure of whether a treatment works, and the latter is a measure of whether the treatment is effective in a variety of settings and can be implemented in those settings.

## Key Terms

**civil commitment laws, 559**
**mental illness, 561**
**dangerousness, 561**
**deinstitutionalization, 562**
**transinstitutionalization, 563**
**criminal commitment, 565**
**diminished capacity, 566**
**competence, 569**
**duty to warn, 569**
**expert witness, 569**
**clinical efficacy axis, 573**
**clinical utility axis, 573**

## Answers to Concept Checks

### 16.1

**1.** mental disorder; **2.** dangerous; **3.** grave disability; **4.** legal; **5.** deinstitutionalization; **6.** transinstitutionalization

### 16.2

**1.** a; **2.** e; **3.** c; **4.** h; **5.** b; **6.** g, f; **7.** d

### 16.3

**1.** d; **2.** c; **3.** a; **4.** e; **5.** b

# Glossary

**Note:** Many familiar words have specialized meanings and usage in psychology. A number of these, used in the text, are defined here.

**abnormal behavior** A psychological dysfunction within an individual that is associated with distress or impairment in functioning and a response that is not typical or culturally expected.

**acetylcholine** Neurotransmitter, pervasive throughout the nervous system, that contributes to movement, attention, arousal, and memory. A deficiency of acetylcholine is found in people with **Alzheimer's disease**.

**actigraph** Small electronic device that is worn on the wrist like a watch and records body movements. This device can be used to record sleep–wake cycles.

**acute onset** Sudden beginning of a disease or disorder (contrast with **insidious onset**).

**acute pain** Pain that typically follows an injury and disappears once the injury heals or is effectively treated.

**acute PTSD Posttraumatic stress disorder** diagnosed 1 to 3 months following the traumatic event.

**acute stress disorder** Severe reaction immediately following a terrifying event, often including amnesia about the event, emotional numbing, and **derealization**. Many victims later develop **posttraumatic stress disorder**.

**addiction** Informal term for **substance dependence**.

**adoption studies** In genetics research, the study of first-degree relatives reared in different families and environments. If they share common characteristics, such as a disorder, this finding suggests that those characteristics have a genetic component.

**advanced sleep phase type** Type of circadian rhythm problem, not a *DSM-IV-TR* disorder, involving a persistent pattern of early sleep onset and awakening times.

**affect** Conscious, subjective aspect of an **emotion** that accompanies an action at a given time.

**age of onset** Person's age when developing or exhibiting symptoms of a disease or condition.

**agnosia** Inability to recognize and name objects; may be a symptom of **dementia** or other brain disorders.

**agonist** Chemical substance that effectively increases the activity of a **neurotransmitter** by imitating its effects.

**agonist substitution** Replacement of a drug on which a person is dependent with one that has a similar chemical makeup, an **agonist**. Used as a treatment for **substance dependence**.

**agoraphobia Anxiety** about being in places or situations from which escape might be difficult.

**agreeableness** One of the dimensions of the five-factor model of personality and individual differences, involving being warm, kind, and trusting as opposed to hostile, selfish, and mistrustful.

**AIDS-related complex (ARC)** Group of minor health problems such as weight loss, fever, and night sweats that appears after HIV infection but before development of full-blown AIDS.

**akinesia Extrapyramidal symptom** involving slow motor activity, an expressionless face, and emotionless speech.

**alcohol** By-product of the **fermentation** of yeasts, sugar, and water; the most commonly used and abused **depressant** substance.

**alcohol dehydrogenase (ADH)** Enzyme that helps humans metabolize **alcohol**. Different levels of its subtypes may account for different susceptibilities to disorders such as **fetal alcohol syndrome**.

**alcohol use disorders** Cognitive, biological, behavioral, and social problems associated with **alcohol** use and abuse.

**alogia** Deficiency in the amount or content of speech, a disturbance often seen in people with **schizophrenia**.

**alpha adrenergic receptors** Group of nervous system **receptors** stimulated by the **neurotransmitter norepinephrine**.

**alpha waves** Regular pattern of brain-wave voltage changes typical of calm relaxation.

**alters** Shorthand term for alter egos, the different personalities or identities in **dissociative identity disorder**.

**altruistic suicide** Formalized suicide approved of and even expected by some cultures.

**Alzheimer's disease** "Strange disease of the cerebral cortex" that causes an "atypical form of senile dementia," discovered in 1906 by German **psychiatrist** Alois Alzheimer.

**amnestic disorder** Deterioration in the ability to transfer information from short- to long-term memory, in the absence of other **dementia** symptoms, as a result of **head trauma** or drug abuse.

**amniocentesis** Prenatal medical procedure that allows the detection of abnormalities (for example, **Down syndrome**) in the developing fetus. It involves removal and analysis of amniotic fluid from the mother.

**amok** One of several running disorders seen in non-Western cultures—as in "running amok"—in which individuals enter a trancelike state and may commit violent acts. Later, they will have amnesia about the episode.

**amphetamine Stimulant** medication used to treat hypersomnia by keeping the person awake during the day, and to treat **narcolepsy**, including sudden onset episodes, by suppressing **rapid eye movement sleep**.

**amphetamine use disorders** Psychological, biological, behavioral, and social problems associated with **amphetamine** use and abuse.

**amygdala** Part of the brain's limbic system that regulates **emotions** and the ability to learn and control impulses; figures prominently in some **psychopathology**.

**amyloid plaque** Clusters of dead **neurons** found during autopsy in the brains of people with **Alzheimer's disease**. Also known as *neuritic* or *senile plaque.*

**amyloid precursor protein** Large protein, controlled by a **gene** on chromosome 21, that breaks down to contribute to the **amyloid plaque** characteristic of people with **Alzheimer's disease**.

**amyloid protein** Solid, waxy substance forming the core of the **amyloid plaque** characteristic of people with **Alzheimer's disease**.

**analgesic rebound headache** Headache, more severe than the original one, that occurs after the medication used to treat headache pain has "worn off."

**analog model** Approach to research that employs subjects who are similar to clinical clients, allowing **replication** of a clinical problem under controlled conditions.

**anandamide** Neurochemical that seems to be a naturally occurring version of the active chemical in **marijuana**.

**angina pectoris** Chest pain caused by partial blockage of the arteries that supply blood to the heart.

**anhedonia** Inability to experience pleasure, associated with some **mood** and schizophrenic disorders.

**animal phobia** Unreasonable, enduring **fear** of animals or insects that usually develops early in life.

**anomic suicide** Suicide motivated by loss and confusion caused by a major life disruption.

**anorexia nervosa** Eating disorder characterized by recurrent food refusal, leading to dangerously low body weight.

**Antabuse** See **disulfiram**.

**antagonist** In **neuroscience**, a chemical substance that decreases or blocks the effects of a **neurotransmitter**.

**antagonist drugs** Medications that block or counteract the effects of psychoactive drugs.

**antibodies** Highly specific molecules called immunoglobulins produced by **B cells** to combine with and neutralize **antigens**.

**antigens** Foreign materials that enter the body, including bacteria and parasites.

**antisocial personality disorder** Cluster B (dramatic, emotional, or erratic) **personality disorder** involving a pervasive pattern of disregard for and violation of the rights of others. Similar to the non-*DSM-IV-TR* label **psychopathy** but with greater emphasis on overt behavior rather than **personality traits**.

**anxiety Mood** state characterized by marked **negative affect** and bodily symptoms of tension in which a person apprehensively anticipates future danger or misfortune. Anxiety may involve feelings, behaviors, and physiological responses.

**Anxiety Disorders Interview Schedule-IV (ADIS-IV)** Specialized, structured interview protocol to assess **anxiety** and related disorders.

**apathy** See **avolition**.

**aphasia** Impairment or loss of language skills resulting from brain damage caused by **stroke**, **Alzheimer's disease**, or other illness or trauma.

**apnea** See **sleep apnea**.

**apolipoprotein E (apo E)** Protein involved in the transport of cholesterol. High concentration of one subtype, controlled by a **gene** on chromosome 19, is associated with **Alzheimer's disease**.

**arrhythmia** Irregular heartbeat.

**Asperger's disorder Pervasive developmental disorder** characterized by impairments in social relationships and restricted or unusual behaviors, but without the language delays seen in **autism**.

**assertiveness training** Instruction in which individuals learn to cope with **stress** by rehearsing ways to protect their time and personal rights in appropriate ways to avoid being exploited and feeling used. For example, caregivers of people with **Alzheimer's disease** learn assertiveness to prevent them from resorting to abuse in frustration.

**assessment gender bias** Possibility that gender differences in the reported prevalence or **diagnosis** of certain diagnostic categories may be the result of prejudice in the assessment measures or the ways they are used.

**association studies** Research strategies for comparing **genetic markers** in groups of people with and without a particular disorder.

**associative splitting** Separation among basic functions of human personality (for example, cognition, **emotion**, and perception) seen by some as the defining characteristic of **schizophrenia**.

**asylum** Safe refuge; specifically, an institution to house mentally disordered people.

**atherosclerosis** Process by which a fatty substance or plaque builds up inside arteries to form obstructions.

**attention deficit/hyperactivity disorder (ADHD)** Developmental disorder featuring maladaptive levels of inattention, excessive activity, and impulsiveness.

**atypical depressive episode** Depressive episode characterized by some ability to experience interest and pleasure, increased **anxiety**, overeating, and oversleeping.

**auditory hallucinations** Psychotic disturbance in perception in which a person hears sounds or voices although these are not real or actually present. The voices are often critical, accusatory, or demanding.

**augmentative communication strategies** Pictures or computer aids to assist people with communication deficits so that they can communicate.

**autistic disorder (autism) Pervasive developmental disorder** characterized by significant impairment in social interactions and communication and restricted patterns of behavior, interest, and activity.

**autoimmune disease** Condition in which the body's **immune system** attacks healthy tissue rather than **antigens**.

**autonomic nervous system** Part of the **peripheral nervous system** that regulates cardiovascular (heart and blood vessel), endocrine **(hormone)**, and digestive functions. Includes the **sympathetic** and **parasympathetic nervous systems**.

**autonomic restrictors** Term for people with **generalized anxiety disorder** because they show lower heart rate, blood pressure, skin conductance, and respiration rate activity than do people with other anxiety disorders.

**avoidant personality disorder** Cluster C (anxious or fearful) **personality disorder** featuring a pervasive pattern of social inhibition, feelings of inadequacy, and hypersensitivity to criticism.

**avolition** *Apathy,* or the inability to initiate or persist in important activities.

**axes** Several dimensions for which information is provided in *DSM-IV-TR* **diagnosis** protocols—for example, clinical disorders and medical conditions.

**axon** Nerve cell branches that transmit outgoing electrochemical impulses to other **neurons**.

**B cells** Special type of white blood cells produced in bone marrow. They release into the **humoral branch** of the **immune system** molecules that circulate in the blood to seek, identify, and neutralize **antigens**.

**barbiturates** Sedative (and addictive) drugs including Amytal, Seconal, and Nembutal that are used as sleep aids.

**bariatric surgery** Surgical approach to extreme **obesity**, usually accomplished by stapling the stomach to create a small stomach pouch or bypassing the stomach through gastric bypass surgery.

**basal ganglia** Brain area at the base of the **forebrain** that seems to control motor behavior and to be involved in **obsessive-compulsive disorder**.

**baseline** Measured rate of a behavior before introduction of an intervention that allows comparison and assessment of the effects of the intervention.

**behavioral assessment** Measuring, observing, and systematically evaluating (rather than inferring) the client's thoughts, feelings, and behavior in the actual problem situation or context.

**behavioral inhibition system (BIS)** Brain circuit in the **limbic system** that responds to threat signals by inhibiting activity and causing **anxiety**.

**behavioral medicine** Interdisciplinary approach applying behavioral science to the prevention, **diagnosis**, and treatment of medical problems.

**behavioral model** Explanation of human behavior, including dysfunction, based on principles of learning and adaptation derived from experimental psychology.

**behavioral rehearsal Behavior therapy** technique in which the client practices coping with troublesome or anxiety-arousing situations in a safe and supervised situation.

**behaviorism** Explanation of human behavior, including dysfunction, based on principles of learning and adaptation derived from experimental psychology.

**behavior rating scales** Structured assessment instruments used before and during treatment to evaluate the frequency and severity of specific behaviors.

**behavior therapy** Array of therapy methods based on the principles of behavioral and **cognitive science**, as well as principles of learning as applied to clinical problems. It considers specific behaviors rather than inferred conflicts as legitimate targets for change.

**Bender Visual-Motor Gestalt Test** Neuropsychological test for children in which they copy a variety of lines and shapes.

**benzodiazepines** Antianxiety drugs including Valium, Xanax, Dalmane, and Halcion also used to treat insomnia. Effective against **anxiety** (and, at high potency, panic disorder), they show some side effects, such as some cognitive and motor impairment, and may result in **substance dependence**. **Relapse** rates are extremely high when the drug is discontinued.

**beta adrenergic receptors** Group of nervous system **receptors** stimulated by the **neurotransmitter norepinephrine** to increase blood pressure and heart rate. Drugs called beta-blockers act at this level to control high blood pressure.

**binge** Relatively brief episode of uncontrolled, excessive consumption, usually of food or **alcohol**.

**binge-eating disorder (BED)** Pattern of eating involving distress-inducing **binges** not followed by purging behaviors; being considered as a new *DSM* diagnostic category.

**biofeedback** Use of physiological monitoring equipment to make individuals aware of their own bodily functions, such as blood pressure or brain waves, that they cannot normally access, with the purpose of controlling these functions.

**biological model** Explanation of psychological dysfunction that primarily emphasizes brain disorder or illness as the cause.

**bipolar I disorder** Alternation of **major depressive episodes** with full **manic episodes**.

**bipolar II disorder** Alternation of **major depressive episodes** with **hypomanic episodes** (not full manic episodes).

**bisexuality** Attraction to both same- and opposite-sex sexual partners.

**black box** Concept of the inner workings of the organism, such as thoughts and feelings that cannot be observed directly.

**blind sight** Phenomenon in which a person is able to perform visual functions while having no awareness or memory of these abilities. Also called *unconscious vision.*

**blood–injury–injection phobia** Unreasonable **fear** and avoidance of exposure to blood, injury, or the possibility of an injection. Victims experience fainting and a drop in blood pressure.

**body dysmorphic disorder (BDD) Somatoform disorder** featuring a disruptive preoccupation with some imagined defect in appearance (“imagined ugliness”).

**borderline personality disorder** Cluster B (dramatic, emotional, or erratic) **personality disorder** involving a pervasive pattern of instability of interpersonal relationships, self-image, affects, and control over impulses.

**bradykinesia** Slowed body movements, as occur in **Parkinson’s disease**.

**brain circuits Neurotransmitter** currents or neural pathways in the brain.

**brain stem** Ancient lower part of the brain responsible for many life-sustaining automatic functions, such as breathing and coordinated movement.

**breathalyzer test** Measure of **alcohol** intoxication that uses a breath sample because some consumed alcohol is vaporized in the lungs and exhaled.

**breathing-related sleep disorders** Sleep disruption leading to excessive sleepiness or insomnia, caused by a breathing problem such as interrupted **(sleep apnea)** or labored **(hypoventilation)** breathing.

**Brief Psychiatric Rating Scale** Behavior rating scale used to assess the severity of patient problem areas, such as guilt feelings and preoccupation with health.

**brief psychotic disorder** Psychotic disturbance involving **delusions**, **hallucinations**, or **disorganized speech** or behavior but lasting less than 1 month; often occurs in reaction to a stressor.

**Briquet’s syndrome** Obsolete term for **somatization disorder**.

**bulimia nervosa** Eating disorder involving recurrent episodes of uncontrolled excessive **(binge)** eating followed by compensatory actions to remove the food (for example, deliberate vomiting, laxative abuse, and excessive exercise).

**caffeine use disorders** Cognitive, biological, behavioral, and social problems associated with the use and abuse of caffeine.

**cancer** Category of often-fatal medical conditions involving abnormal cell growth and malignancy.

**cannabinoids** Family of chemicals in **marijuana** believed to be responsible for its mood- and behavior-altering ability.

**cardiovascular disease** Afflictions in the mechanisms, including the heart, blood vessels, and their controllers, responsible for transporting blood to the body’s tissues and organs. Psychological factors may play important roles in such diseases and their treatments.

**cardiovascular system** Heart, blood vessels, and their controlling mechanisms, all of which transport blood and nutrients to the tissues of the body.

**case study method** Research procedure in which a single person or small group is studied in detail. The method does not allow conclusions about cause-and-effect relationships, and findings can be generalized only with great caution (contrast with **single-case experimental design**).

**castration anxiety** In **psychoanalysis**, the **fear** in young boys that they will be mutilated genitally because of their lust for their mothers.

**catalepsy** Motor movement disturbance seen in people with some psychoses and **mood disorders** in which body postures are waxy and can be “sculpted” to remain fixed for long periods.

**cataplexy** Sudden loss of muscle tone that accompanies **narcolepsy**.

**catatonia** Disorder of movement involving immobility or excited agitation.

**catatonic immobility** Disturbance of motor behavior in which the person remains motionless, sometimes in an awkward posture, for extended periods.

**catatonic type of schizophrenia** Type of **schizophrenia** in which motor disturbances (rigidity, agitation, and odd mannerisms) predominate.

**catecholamine** Outdated, simplistic theory of the **etiology** of **mood disorders** stating that **norepinephrine** (a catecholamine) excess causes **mania**, and that low levels of it cause some forms of depression.

**catharsis** Rapid or sudden release of emotional tension thought to be an important factor in psychoanalytic therapy.

**caudate nucleus** Brain structure; part of the **basal ganglia** that controls motor behavior and is implicated in **obsessive-compulsive disorder**.

**cellular branch** Branch of the **immune system** using specialized cells to protect the body cells against viral and parasite infections.

**central nervous system** Brain and spinal cord.

**central sleep apnea** Brief periods of cessation in respiratory activity during sleep that may be associated with **central nervous system** disorders. Most clients awaken often as a result but do not report sleepiness and may be unaware of any problem.

**cerebellum** Part of the **hindbrain** in the **brain stem** that controls motor coordination and may be involved in **autism**.

**cerebral cortex** Largest part of the **forebrain**, divided into two hemispheres; responsible for human functions such as perceiving, reasoning, planning, creating, and remembering.

**chemical imbalance** Relative excess or deficit in brain chemicals, such as

**neurotransmitters**, that may be implicated in some **psychological disorders**.

**childhood disintegrative disorder Pervasive developmental disorder** involving severe regression in language, adaptive behavior, and motor skills after a 2- to 4-year period of normal development.

**choking phobia Fear** and avoidance of swallowing pills, foods, and fluids, which may lead to significant weight loss. Also known as *hypersensitive gag reflex* or *globus hystericus.*

**chorea** Motor problems characterized by involuntary limb movements.

**chorionic villus sampling (CVS)** A genetic test conducted during early pregnancy that samples cells found in the placenta (chorionic villi) and assesses possible genetic or chromosomal problems in the fetus.

**chronic fatigue syndrome (CFS)** Incapacitating exhaustion following only minimal exertion, accompanied by fever, headaches, muscle and joint pain, depression, and **anxiety**.

**chronic pain** Enduring pain that does not decrease over time; may occur in muscles, joints, and the lower back, and may be caused by enlarged blood vessels or degenerating or cancerous tissue. Other significant factors are social and psychological.

**chronic PTSD Posttraumatic stress disorder** that endures longer than 3 months and is associated with greater avoidance and a higher likelihood of **comorbidity** with additional disorders.

**chronic stage** Final of E. Morton Jellinek's four stages identified in the progression of alcoholism, where the individual's primary daily activities revolve around obtaining and drinking **alcohol**.

**chronological age** Person's age in calendar years.

**circadian rhythm sleep disorders** Sleep disturbances resulting in sleepiness or insomnia, caused by the body's inability to synchronize its sleep patterns with the current pattern of day and night.

**civil commitment laws** Legal proceedings that determine a person is mentally disordered and may be hospitalized, even involuntarily.

**classical categorical approach Classification** method founded on the assumption of clear-cut differences among disorders, each with a different known cause.

**classical conditioning** Fundamental learning process first described by Ivan Pavlov. An event that automatically elicits a response is paired with another stimulus event that does not (a neutral stimulus). After repeated pairings, the neutral stimulus becomes a **conditioned stimulus** that by itself can elicit the desired response.

**classification** Assignment of objects or people to categories on the basis of shared characteristics.

**clinical assessment** Systematic evaluation and measurement of psychological, biological, and social factors in a person presenting with a possible **psychological disorder**.

**clinical description** Details of the combination of behaviors, thoughts, and feelings of an individual that make up a particular disorder.

**clinical efficacy axis** One of a proposed set of guidelines for evaluating clinical interventions on the evidence of their effectiveness (compare with **clinical utility axis**).

**clinical psychologist** Person who has earned a Ph.D. or related degree (for example, Psy.D.) in psychology and is trained to conduct research into the causes and treatment of severe **psychological disorders**, as well as to diagnose, assess, and treat them.

**clinical significance** Degree to which research findings have useful and meaningful applications to real problems.

**clinical utility axis** One of a proposed set of guidelines for evaluating clinical interventions by whether they can be applied effectively and cost effectively in real clinical settings (compare with **clinical efficacy axis**).

**clonidine** Medical treatment for **hypertension** that is often used to reduce the negative symptoms of **withdrawal** from **opiates**.

**clozapine** One of the newer medications for **schizophrenia** (trade name Clozaril), a weak **dopamine antagonist** that seems effective in some previously untreatable cases and with fewer serious side effects.

**cocaine** Derivative of coca leaves used medically as a local anesthetic and narcotic; often a substance of abuse.

**cocaine use disorders** Cognitive, biological, behavioral, and social problems associated with the use and abuse of **cocaine**.

**codeine Opiate**; a mild, medical narcotic derived from **morphine**.

**cognitive-behavioral treatment (CBT)** Group of treatment procedures aimed at identifying and modifying faulty thought processes, attitudes and attributions, and problem behaviors; often used synonymously with **cognitive therapy**.

**cognitive relaxation** Use of meditation or imagery to combat **anxiety** that may result from sleeplessness.

**cognitive restructuring Cognitive therapy** procedure used to change negative or unrealistic thoughts or attributions.

**cognitive science** Field of study that examines how humans and other animals acquire, process, store, and retrieve information.

**cognitive therapy** Treatment approach that involves identifying and altering negative thinking styles related to **psychological disorders** such as depression and **anxiety** and replacing them with more positive beliefs and attitudes—and, ultimately, more adaptive behavior and coping styles.

**cohort** Participants in each age group of a study with a **cross-sectional design**.

**cohort effect** Observation that people of different age groups differ in their values and experiences.

**collective unconscious** Accumulated wisdom of a culture collected and remembered across generations, a psychodynamic concept introduced by Carl Jung.

**communication disorders** Problems in transmitting or conveying information, including stuttering, **selective mutism**, and **expressive language disorder**.

**community intervention** Approach to treating and preventing disorders by directing action at the organizational, agency, and community levels rather than at individuals.

**comorbidity** Presence of two or more disorders in an individual at the same time.

**comparative treatment research Outcome research** that contrasts two or more treatment methods to determine which is most effective.

**competence** Ability of legal defendants to participate in their own defense and understand the charges and the roles of the trial participants.

**Comprehensive System** Standardized system of administering and scoring the **Rorschach inkblot test** that seeks to improve its **reliability** and **validity**.

**compulsions** Repetitive, ritualistic, time-consuming behaviors or mental acts a person feels driven to perform.

**computerized axial tomography (CAT) scan (CT scan)** Noninvasive imaging procedure useful in identifying abnormalities in the structure or shape of the brain.

**concurrent (descriptive) validity** Condition of testing in which the results from one test correspond to the results of other measures of the same phenomenon.

**conditioned response (CR)** Learned reaction, similar to the **unconditioned response**, elicited by a **conditioned stimulus** following **classical conditioning**.

**conditioned stimulus (CS)** Environmental event that acquires the ability to elicit a learned response as a result of **classical conditioning** associated with an **unconditioned stimulus**.

**conditioning** Process by which behaviors can be learned or modified through interaction with the environment. See **classical conditioning** and **operant conditioning**.

**confound** Any factor occurring in a study that makes the results uninterpretable because its effects cannot be separated from those of the variables being studied.

**confounding variable** Variable in a research study that was not part of the intended design and that may contribute to changes in the **dependent variable**.

**conscientiousness** One of the dimensions of the five-factor model of personality and individual differences involving being organized, thorough, and reliable as opposed to careless, negligent, and unreliable.

**construct validity** Degree to which signs and symptoms used to categorize a disorder relate to one another while differing from those for other disorders.

**content validity** Degree to which the characteristics of a disorder are a true sample of the phenomenon in question.

**contingency management** Encouragement of reinforcers to promote and maintain desired behaviors and removal of those reinforcers that maintain undesired behaviors.

**control group** Group of individuals in a study who are similar to the experimental subjects in every way but are not exposed to the treatment received by the experimental group. Their presence allows for a comparison of the differential effects of the treatment.

**controlled drinking** An extremely controversial treatment approach to **alcohol** dependence, in which severe abusers are taught to drink in moderation.

**conversion disorder** Physical malfunctioning, such as blindness or paralysis, suggesting neurological impairment but with no organic pathology to account for it.

**conversion hysteria** Obsolete term for **conversion disorder** derived from the Freudian notion that physical symptoms represented a conversion of **unconscious** conflicts into a more acceptable form.

**coping styles** See **defense mechanisms**.

**coronary heart disease (CHD)** Blockage of the arteries supplying blood to the heart muscle; a major cause of death in Western culture, with social and psychological factors involved.

**correlation** Degree to which two variables are associated. In a **positive correlation**, the two variables increase or decrease together. In a **negative correlation**, one variable decreases as the other increases.

**correlation coefficient** Computed statistic reflecting the strength and direction of any association between two variables. It can range from +1.00 through 0.00 (indicating no association) to −1.00, with the absolute value indicating the strength and the sign reflecting the direction.

**correlational study** Research procedure in which variables are measured and compared to detect any association but are not manipulated. Conclusions about cause-and-effect relationships are not permissible.

**corticosteroids Hormones**, including **cortisol**, released by the adrenal gland in response to stressors to activate and, later, to turn off the body's **stress** response. Also called **stress hormones**.

**corticotropin-releasing factor (CRF) Neuromodulator hormone** secreted into the blood by the **hypothalamus**. It stimulates the pituitary gland as part of a reaction chain called the **stress** response. It may be implicated in **mood disorders**, as well as physical problems.

**cortisol Stress hormone (corticosteroid)** secreted by the cortex of the adrenal glands as part of the **stress** response.

**counseling psychologist** Person who has earned a Ph.D. or related degree in psychology and is trained to study and treat adjustment and vocational issues in relatively healthy people.

**countertransference** Psychoanalytic concept involving personal issues the therapist brings to professional relationships with clients.

**course** Pattern of development and change of a disorder over time.

**course modifiers** Patterns of development in a disorder that help predict its future course. These include recurrence, time sequences, and **seasonal pattern**.

**covert sensitization** Cognitive-behavioral intervention to reduce unwanted behaviors by having clients imagine the extremely aversive consequences of the behaviors and establish negative rather than positive associations with them.

**crack Cocaine** in a highly potent, solid, rock-like form.

**crack babies** Infants who were exposed to **cocaine** prenatally because of their mothers' use. Their characteristic irritability and high-pitched crying may be caused by abuse or neglect, in addition to the cocaine itself.

**Creutzfeldt–Jakob disease** Extremely rare condition that causes **dementia**.

**criminal commitment** Legal procedure by which a person found not guilty of a crime by reason of **insanity** must be confined in a psychiatric hospital.

**criterion gender bias** Possibility that gender differences in the reported prevalence or **diagnosis** of certain diagnostic categories may be the result of prejudice in the defining criteria for the disorder.

**criterion validity** Extent to which categorization accurately predicts the future **course** of a disorder, whether treated or untreated. See also **predictive validity**.

**cross-generational effect** Limit on the **generalizability** of longitudinal research because the group under study may differ from others in culture and experience.

**cross-sectional design** Methodology to examine a characteristic by comparing individuals of different ages (contrast with **longitudinal design**).

**cross-tolerance** Condition in which a person may replace **addiction** to one drug with addiction to another when the two drugs have similar chemical makeup and act on the same **neurotransmitter receptors**.

**crucial stage** Third of four of E. Morton Jellinek's stages identified in the progression of alcoholism, involving a loss of control of drinking and occasional **binges** of heavy drinking.

**cultural–familial intellectual disability** Mild **intellectual disability** that may be caused largely by environmental influences.

**cyclothymic disorder** Chronic (at least 2 years) **mood disorder** characterized by alternating **mood** elevation and depression levels that are not as severe as **manic** or **major depressive episodes**.

**dangerousness** Tendency to violence that, contrary to popular opinion, is not more likely among mental patients.

**deep sleep** Sleep stage characterized by slow brain-wave **(delta wave)** patterns. A person in deep sleep is difficult to rouse and slow to become alert.

**defense mechanisms** Common patterns of behavior, often adaptive coping styles when they occur in moderation, observed in response to particular situations. In **psychoanalysis**, these are thought to be **unconscious** processes originating in the **ego**.

**deinstitutionalization** Systematic removal of people with severe mental illness or **intellectual disability** from institutions like psychiatric hospitals.

**delayed-onset PTSD Posttraumatic stress disorder** with onset more than 6 months after the traumatic event.

**delayed sleep phase type of circadian rhythm sleep disorder** Persistent pattern of late sleep onset and awakening time.

**delirium** Rapid-onset reduced clarity of consciousness and cognition, with confusion, disorientation, and deficits in memory and language.

**delta waves** Relatively slow and irregular pattern of brain waves typical of the deepest, most relaxed stage of sleep. This is the time when sleeping **panic attacks** may occur. Delta activity during wakefulness may indicate brain dysfunction. Also known as *slow wave sleep.*

**delusion** **Psychotic symptom** involving disorder of thought content and presence of strong beliefs that are misrepresentations of reality.

**delusional disorder** Psychotic disorder featuring a persistent belief contrary to reality **(delusion)** but no other symptoms of **schizophrenia**.

**delusion of grandeur** **Psychotic symptom**; people's unfounded belief that they are more famous or important than is true.

**delusion of persecution** People's unfounded belief that others seek to harm them.

***démence précoce*** French-language form of **dementia praecox**.

**dementia** Gradual-onset deterioration of brain functioning, involving memory loss, inability to recognize objects or faces, and problems in planning and abstract reasoning. These are associated with frustration and discouragement.

**dementia of the Alzheimer's type** Gradual onset of cognitive deficits caused by **Alzheimer's disease**, principally identified by a person's inability to recall newly or previously learned material. The most common form of **dementia**.

**dementia praecox** Latin term meaning "premature loss of mind," an early label for what is now called **schizophrenia**, emphasizing the disorder's frequent appearance during adolescence. Called *démence précoce* in France.

**dendrite** Nerve cell branches that receive incoming electrochemical information for transmission along the **neuron**.

**dependent personality disorder** Cluster C (anxious or fearful) **personality disorder** characterized by a person's pervasive and excessive need to be taken care of, a condition that leads to submissive and clinging behavior and fears of separation.

**dependent variable** In an experimental study, the phenomenon that is measured and expected to be influenced (compare with **independent variable**).

**depersonalization** Altering of perception that causes people to temporarily lose a sense of their own reality; most prevalent in people with the **dissociative disorders**. There is often a feeling of being outside observers of their own behavior.

**depersonalization disorder** **Dissociative disorder** in which feelings of **depersonalization** are so severe they dominate the client's life and prevent normal functioning.

**depressants** **Psychoactive substances** that result in behavioral sedation, including **alcohol** and the sedative, hypnotic, and anxiolytic drugs.

**depressive cognitive triad** Thinking errors in depressed people negatively focused in three areas: themselves, their immediate world, and their future.

**depressive personality disorder** Pervasive pattern dominated by dejection, self-criticism, and a judgmental stance toward other people; under consideration as a future *DSM* category.

**depressive stupor (catatonic depressive episode)** Rare but severe depressive episode experienced by someone with a **mood disorder**, featuring, usually, substantial reduction in spontaneous motor movement or, occasionally, agitation or odd mannerisms.

**derailment** See **loose associations**.

**derealization** Situation in which the individual loses a sense of the reality of the external world.

**desire phase** First stage of sexual activity, when sexual urges, thoughts, or fantasies occur, either in reaction to or even in the absence of a stimulating cue.

**deterministic** In genetics, **genes** that lead to nearly a 100% chance of developing the associated disorder. These are rare in the population.

**developmental psychology** Study of changes in behavior that occur over time.

**developmental psychopathology** Study of changes in **abnormal behavior** that occur over time.

**deviation IQ** Intelligence test score that estimates how much a child's school performance will deviate from the average performance of others of the same age.

**dexamethasone suppression test (DST)** Proposed biological test for depression. The test failed to discriminate depression from other disorders.

**diagnosis** Process of determining whether a **presenting problem** meets the established criteria for a specific **psychological disorder**.

**Diagnostic and Statistical Manual, Fourth Edition, Text Revision (*DSM-IV-TR*)** Current version of the official **classification** system for **psychological disorders**, published by the American Psychiatric Association.

**dialectical behavioral therapy (DBT)** Promising treatment for **borderline personality disorder** that involves exposing the client to stressors in a controlled situation, as well as helping the client regulate **emotions** and cope with stressors that might trigger suicidal behavior.

**diastolic blood pressure** Blood pressure level when the heart is at rest or between heartbeats.

**diathesis–stress model** **Hypothesis** that both an inherited tendency (a **vulnerability**) and specific stressful conditions are required to produce a disorder.

**dimensional approach** Method of categorizing characteristics on a continuum rather than on a binary, either-or, or all-or-none basis.

**dimethyltryptamine (DMT)** Natural **hallucinogen** from the bark of trees that grow in Central and South America.

**diminished capacity** Evidence of an abnormal mental condition in people that causes criminal charges against them requiring intent or knowledge to be reduced to lesser offenses requiring only reckless or criminal neglect.

**directionality** Possibility that when two variables, A and B, are correlated variable A causes variable B or variable B causes variable A.

**discrimination training** Arrangement of experiences in which the person or animal learns to respond under certain conditions and not to respond under other conditions.

**disease conviction** Core feature of **hypochondriasis**; people's firm belief that they currently have a disease, based on the misinterpretation of their own symptoms and sensations.

**disease model of dependence** View that drug dependence is caused by a physiological disorder. This implies the user is a blameless victim of an illness.

**disorder of written expression** Condition in which writing performance is significantly below the standard for that age level.

**disorganized speech** Style of talking often seen in people with **schizophrenia**, involving incoherence and a lack of typical logic patterns.

**disorganized type of schizophrenia** Type of **schizophrenia** featuring disrupted speech and behavior, disjointed **delusions** and **hallucinations**, and silly or **flat affect**.

**displacement** **Defense mechanism** in which a person directs a problem impulse toward a safe substitute.

**dissociation** Detachment or loss of integration between identity or reality and consciousness.

**dissociative amnesia** **Dissociative disorder** featuring the inability to recall personal information, usually of a stressful or traumatic nature.

**dissociative disorder** Disorder in which individuals feel detached from themselves or their surroundings and reality, experience, and identity may disintegrate.

**dissociative fugue** **Dissociative disorder** featuring sudden, unexpected travel away from home, along with an inability to recall the past, sometimes with assumption of a new identity.

**dissociative identity disorder (DID)** Formerly known as multiple personality disorder; a disorder in which as many as 100 personalities or fragments of personalities coexist within one body and mind.

**dissociative trance disorder (DTD)** Altered state of consciousness in which people firmly believe they are possessed by spirits; considered a disorder only where there is distress and dysfunction.

**disulfiram** Chemical used as an aversion treatment for heavy drinking because it causes a buildup in the body of an **alcohol** by-product, making the person vomit after drinking. Clients must continue taking it for the chemical to remain effective. Also known as *Antabuse.*

**dominant gene** One **gene** of any pair of genes that determines a particular trait.

**dopamine Neurotransmitter** whose generalized function is to activate other **neurotransmitters** and to aid in exploratory and pleasure-seeking behaviors (thus balancing **serotonin**). A relative excess of **dopamine** is implicated in **schizophrenia** (although contradictory evidence suggests the connection is not simple), and its deficit is involved in **Parkinson's disease**.

**dopaminergic system** Parts of the nervous system activated by the **neurotransmitter dopamine**; involved in many functions, including the experience of reward.

**dorsal horns of the spinal cord** Sections of the spinal cord responsible for transmitting sensory input to the brain. They function as a "gate" that allows transmission of pain sensations if the stimulation is sufficiently intense.

**double bind communication** According to an obsolete, unsupported theory, the practice of transmitting conflicting messages that was thought to cause **schizophrenia**.

**double-blind control** Procedure in outcome studies that prevents bias by ensuring that neither the subjects nor the providers of the experimental treatment know who is receiving treatment and who is receiving placebo.

**double depression** Severe **mood disorder** typified by **major depressive episodes** superimposed over a background of **dysthymic disorder**.

**Down syndrome** Type of **intellectual disability** caused by a chromosomal aberration (chromosome 21) and involving characteristic physical appearance. Sometimes known as trisomy 21.

**dream analysis** Psychoanalytic therapy method in which dream contents are examined as symbolic of **id** impulses and **intrapsychic conflicts**.

**duty to warn** Mental health professional's responsibility to break confidentiality and notify the potential victim whom a client has specifically threatened.

**dysfunctional attitudes** Cognitive errors seen in depressed individuals, who may automatically assume the worst, draw negative conclusions arbitrarily, and treat minor problems as major ones.

**dyslexia** Learning disability involving problems in reading.

**dysmorphophobia** Literally, "fear of ugliness," an obsolete term for **body dysmorphic disorder**.

**dysphoric manic episode** See **mixed manic episode**.

**dyssomnias** Problems in getting to sleep or in obtaining sufficient quality sleep.

**dysthymic disorder Mood disorder** involving persistently depressed **mood**, with low self-esteem, **withdrawal**, pessimism, or despair, present for at least 2 years, with no absence of symptoms for more than 2 months.

**echolalia** Repetition or echoing of the speech of others, a normal intermediate step in the development of speech skills. Originally thought to be a unique symptom of **autism**, it is now seen as evidence of developmental delay involved in that disorder.

**echoplanar magnetic resonance imaging** Experimental version of **magnetic resonance imaging** that can make rapid multiple sequential images of the brain as it functions.

**echopraxia** The involuntary imitation of the movement of another person.

**educable intellectual disability** Obsolete term referring to level of intellectual disability comparable to the *DSM-IV-TR* "mild" designation that assumes the individual can learn basic academic skills.

**ego** In **psychoanalysis**, the psychical entity responsible for finding realistic and practical ways to satisfy **id** drives.

**egoistic suicide** Suicide that occurs in the context of diminished social supports, as in the case of some elderly people who have lost friends and family contacts.

**ego psychology** Derived from **psychoanalysis**, this theory emphasizes the role of the **ego** in development and attributes **psychological disorders** to failure of the ego to manage impulses and internal conflicts. Also known as *self-psychology.*

**Electra complex** In **psychoanalysis**, a young girl's intrapsychic desire to replace her mother, possess her father, and acquire a penis. The resolution of this complex results in development of the **superego**.

**electrocardiogram** Measure of electrical activity generated by heart muscle exertion used to detect and evaluate heart diseases.

**electroconvulsive therapy (ECT)** Biological treatment for severe, chronic depression involving the application of electrical impulses through the brain to produce seizures. The reasons for its effectiveness are unknown.

**electroencephalogram (EEG)** Measure of electrical activity patterns in the brain, taken through electrodes placed on the scalp.

**electromyogram (EMG)** Measure of muscle movement.

**electrooculogram (EOG)** Measure of eye muscle movement particularly relevant to detecting dream stages during sleep.

**emotion** Pattern of action elicited by an external event and a feeling state, accompanied by a characteristic physiological response.

**emotional stability** One of the dimensions of the five-factor model of personality and individual differences, involving being even-tempered as opposed to nervous, moody, and temperamental.

**emotion contagion** Situation in which an emotional reaction spreads from one individual to others nearby.

**empathy** Condition of sharing and understanding the **emotions** of another person.

**endocrine system** Network of glands that affect bodily functions by releasing **hormones** into the bloodstream. Some endocrine activity is implicated in **psychological disorders**.

**endogenous opioids** Substances occurring naturally throughout the body that function like **neurotransmitters** to shut down pain sensation even in the presence of marked tissue damage. These may contribute to psychological problems such as eating disorders. Also known as *endorphins* or *enkephalins.*

**endophenotypes** Genetic mechanisms that contribute to the underlying problems causing the symptoms and difficulties experienced by people with **psychological disorders**.

**endorphins** See **endogenous opioids**.

**enkephalins** See **endogenous opioids**.

**epidemiology Psychopathology** research method examining the prevalence, distribution, and consequences of disorders in populations.

**epigenetics** The study of factors other than inherited DNA sequence, such as new learning or stress, that alter the phenotypic expression of genes.

**episodic course** Pattern of a disorder alternating between recovery and recurrence.

**equifinality Developmental psychopathology** principle that a behavior or disorder may have several causes.

**erotomanic type** Type of **delusional disorder** featuring belief that another person, usually of higher status, is in love with the individual.

**erotophobia** Learned negative reaction to or attitude about sexual activity, perhaps developed as a result of a negative or even traumatic event, such as rape.

**essential hypertension** High blood pressure with no verifiable physical cause, which makes up the overwhelming majority of high blood pressure cases.

**etiology** Cause or source of a disorder.

**event-related potential (ERP)** Brain's electrical reaction to a psychologically meaningful environment event, as measured by the **electroencephalogram**. Also known as evoked potential.

**exhibitionism** Sexual gratification attained by exposing genitals to unsuspecting strangers.

**exorcism** Religious ritual that attributes disordered behavior to possession by demons and seeks to treat the individual by driving the demons from the body.

**expectancy effect** People's response to a substance on the basis of their beliefs about it, even if it contains no active ingredient. This phenomenon demonstrates that cognitive, as well as physiological, factors are involved in drug reaction and dependence.

**experiment** Research method that can establish causation by manipulating the variables in question and controlling for alternative explanations of any observed effects.

**expert witness** Person who because of special training and experience is allowed to offer opinion testimony in legal trials.

**explicit memory** Good recollection of actual events (contrast with **implicit memory**).

**expressed emotion (EE)** Hostility, criticism, and overinvolvement demonstrated by some families toward a family member with a **psychological disorder**. This can often contribute to the person's **relapse**.

**expressive language** Communication with words.

**expressive language disorder** An individual's problems in spoken communication, as measured by significantly low scores on standardized tests of **expressive language** relative to nonverbal intelligence test scores. Symptoms may include a markedly limited vocabulary or errors in verb tense.

**extensive support intellectual disability** Intellectual disability level characterized by the long-term and regular care required for individuals with this degree of disability.

**external validity** Extent to which research findings generalize, or apply, to people and settings not involved in the study.

**extinction** Learning process in which a response maintained by **reinforcement** in **operant conditioning** or pairing in **classical conditioning** decreases when that reinforcement or pairing is removed; also the procedure of removing that reinforcement or pairing.

**extrapyramidal symptoms** Serious side effects of **neuroleptic** medications resembling the motor difficulties of **Parkinson's disease**. They include **akinesia** and **tardive dyskinesia**. Also called *parkinsonian symptoms.*

**extroversion** One of the dimensions of the five-factor model of personality and individual differences, involving being talkative, assertive, and active as opposed to silent, passive, and reserved.

**eye-tracking** See **smooth-pursuit eye movement**.

**face validity** Condition of testing in which test items appear plausible for their intended purposes, even if they are not truly valid discriminators.

**facial agnosia** Type of **agnosia** characterized by a person's inability to recognize even familiar faces.

**factitious disorder** Nonexistent physical or **psychological disorder** deliberately faked for no apparent gain except possibly sympathy and attention.

**failure to thrive** Stunted physical growth and maturation in children, often associated with psychosocial factors such as lack of love and nurturing.

**false negative** Assessment error in which no pathology is noted (that is, test results are negative) when one is actually present.

**false positive** Assessment error in which pathology is reported (that is, test results are positive) when none is actually present.

**familial aggregation** The extent to which a disorder is found among a patient's relatives.

**family studies** Genetic studies that examine patterns of traits and behaviors among relatives.

**fatalistic suicide** Suicide in the context of a person's hopelessness and loss of the feeling of control over personal destiny.

**fear Emotion** of an immediate alarm reaction to present danger or life-threatening emergencies.

**fearlessness hypothesis** One of the major theories of the **etiology** of **antisocial personality disorder**, stating that psychopaths are less prone to **fear** and thus less inhibited from dangerous or illicit activities.

**female orgasmic disorder** Recurring delay or absence of orgasm in some women following a normal sexual excitement phase, relative to their prior experience and current stimulation. Also known as **inhibited orgasm** (female).

**female sexual arousal disorder** Recurrent inability in some women to attain or maintain adequate lubrication and sexual excitement swelling responses until completion of sexual activity.

**fermentation** Decomposition process by which yeasts, water, and sugar form **alcohol**.

**fetal alcohol syndrome (FAS)** Pattern of problems including learning difficulties, behavior deficits, and characteristic physical flaws, resulting from heavy drinking by the victim's mother when she was pregnant with the victim.

**fetishism** Long-term, recurring, intense sexually arousing urges, fantasies, or behavior involving the use of nonliving, unusual objects, which cause distress or impairment in life functioning.

**fight/flight system (FFS)** Brain circuit in animals that when stimulated causes an immediate alarm and escape response resembling human **panic**.

**fixation** In **psychoanalysis**, stopping or concentrating at a psychosexual stage because of a lack of appropriate gratification at that stage.

**flashback** Sudden, intense reexperiencing of a previous, usually traumatic, event.

**flat affect** Apparently emotionless demeanor (including toneless speech and vacant gaze) when a reaction would be expected.

**flight or fight response** Biological reaction to alarming stressors that musters the body's resources (for example, blood flow and respiration) to resist or flee a threat.

**fluoxetine Selective-serotonin reuptake inhibitor** (trade name Prozac) that acts on the serotonergic system as a treatment for depression, **obsessive-compulsive disorder**, and **bulimia nervosa**.

**flurazepam** Long-acting medication for insomnia (trade name Dalmane) that may cause daytime sleepiness.

**forebrain** Top section of the brain that includes the limbic system, **basal ganglia**, **caudate nucleus**, and **cerebral cortex**. Also called *telencephalon.*

**formal observation** Structured recording of behaviors that are measurable and well defined.

**fragile X syndrome** Pattern of **abnormality** caused by a defect in the **X chromosome** resulting in **intellectual disability**, learning problems, and unusual physical characteristics.

**free association** Psychoanalytic therapy technique intended to explore threatening material repressed into the **unconscious**. The patient is instructed to say whatever comes to mind without censoring.

**frenzy witchcraft** Running frenzy disorder among the Navajo tribe that seems equivalent to **dissociative fugue**.

**frontal lobe** Forward section of each cerebral hemisphere, most responsible for thinking, reasoning, memory, the experience of reward, and social behavior and thus most likely to be involved in a range of **psychopathology**.

**frotteurism Paraphilia** in which the person gains sexual gratification by rubbing against unwilling victims in crowds from which they cannot escape.

**functional communication training** Teaching of speech or nonspeech communication skills to replace undesired behavior. The new skills are useful to the person and will be maintained because of the effects they have on others.

**functional genomics** The study of how genes function to create changes in the organism.

**GABA–benzodiazepine system** Chemical benzodiazepines (minor tranquilizers) that facilitate the effects of the **neurotransmitter gamma-aminobutyric acid** in reducing **anxiety**. Such a system suggests the existence of natural benzodiazepines in the nervous system that have not yet been discovered.

**gamma-aminobutyric acid (GABA) Neurotransmitter** that reduces activity across the synapse and thus inhibits a range of behaviors and **emotions**, especially generalized **anxiety**.

**gate control theory of pain** View that psychological factors can enhance or diminish the sensation and perception of pain by influencing the transmission of pain impulses through the section of the spinal cord that acts as a "gate."

**gender identity disorder** Psychological dissatisfaction with biological gender, a disturbance in the sense of identity as a male or female. The primary goal is not sexual arousal but rather to live the life of the opposite gender.

**gender nonconformity** A phenomenon in which pre-pubescent children do not identify with their biological sex, but instead identify strongly with the gender of the opposite sex and display varying degrees of behavior more characteristic of the opposite sex.

**general adaptation syndrome (GAS)** Sequence of reactions to sustained **stress** described by Hans Selye. These stages are alarm, resistance, and exhaustion, which may lead to death.

**generalizability** Extent to which research results apply to a range of individuals not included in the study.

**generalized amnesia** Loss of memory of all personal information, including identity.

**generalized anxiety disorder (GAD)** Anxiety disorder characterized by intense, uncontrollable, unfocused, chronic, and continuous worry that is distressing and unproductive, accompanied by physical symptoms of tenseness, irritability, and restlessness.

**genes** Long deoxyribonucleic acid (DNA) molecules, the basic physical units of heredity that appear as locations on chromosomes.

**genetic linkage analysis** Study that seeks to match the inheritance pattern of a disorder to that of a **genetic marker**. This helps researchers establish the location of the **gene** responsible for the disorder.

**genetic marker** Inherited characteristic for which the chromosomal location of the responsible **gene** is known.

**genital herpes** Incurable sexually transmitted viral disease with alternating periods of dormancy and activity. The active periods involve pain, liquid discharge, itching, and ulcerative lesions, and their recurrence may be influenced by **stress**.

**genome** All of the hereditary information of an organism that is encoded in DNA.

**genotype** Specific genetic makeup of an individual.

**globus hystericus** Sensation of a lump in the throat causing the person difficulty in swallowing, eating, and talking. A conversion symptom or part of **choking phobia**.

**glutamate** Amino acid **neurotransmitter** that excites many different **neurons**, leading to action.

**glutamate system** Excitatory **neurotransmitter** system that may be the avenue by which **alcohol** affects cognitive abilities.

**good premorbid** Outdated **classification** for **schizophrenia**, referring to the quality of social functioning of the individual just before the emergence of the disorder.

**graduated extinction** Monitoring of a desired behavior, such as sleeping or compliance by children, with decreasing frequency to encourage independence.

**grandiose type** Type of **delusional disorder** featuring beliefs of inflated worth, power, knowledge, identity, or a special relationship to a deity or famous person.

**hallucinations Psychotic symptoms** of perceptual disturbance in which things are seen, heard, or otherwise sensed although they are not actually present.

**hallucinogen** Any **psychoactive substance** such as **LSD** or **marijuana** that can produce **delusions**, **hallucinations**, **paranoia**, and altered sensory perception.

**hallucinogen use disorders** Cognitive, biological, behavioral, and social problems associated with the use and abuse of hallucinogenic substances.

**Halstead-Reitan Neuropsychological Battery** Relatively precise instrument that helps identify and locate organic damage by testing various skills, including rhythm, grip, and tactile performance.

**head trauma** Injury to the head and, therefore, to the brain, typically caused by accidents; can lead to cognitive impairments, including memory loss.

**health psychology** Subfield of **behavioral medicine** that studies psychological factors important in health promotion and maintenance.

**hebephrenia** Silly and immature emotionality, a characteristic of some types of **schizophrenia**.

**helper T cells** T-type lymphocyte that enhances the **immune system** response by signaling **B cells** to produce **antibodies** and other **T cells** to destroy **antigens**.

**hermaphrodites** See **intersex individuals**.

**heterosexual behavior** Sexual activity with members of the opposite gender.

**hierarchy of needs** Ranking of human necessities from basic food to self-actualization, proposed by Abraham Maslow.

**high blood pressure** See **hypertension**.

**hindbrain** Lowest part of the **brain stem**; regulates many automatic bodily functions, such as breathing and digestion, and includes the **medulla**, **pons**, and **cerebellum**.

**hippocampus** Part of the brain's **limbic system** that regulates **emotions** and the ability to learn and control impulses; figures prominently in some **psychopathology**.

**histrionic personality disorder** Cluster B (dramatic, emotional, or erratic) **personality disorder** involving a pervasive pattern of excessive emotionality and attention seeking.

**homosexual behavior** Sexual activity with members of the same gender.

**hormone** Chemical messenger produced by the endocrine glands.

**human genome project** Ongoing scientific attempt to develop a comprehensive map of all human **genes**.

**human immunodeficiency virus type 1 (HIV-1)** Disease that causes AIDS.

**humoral branch** One of two main branches of the **immune system**; operates in the blood and other bodily fluids to develop **antibodies** and neutralize **antigens**.

**humoral theory** Ancient belief that **psychological disorders** were caused by imbalances in bodily **humors** or fluids.

**humors** Bodily fluids (blood, black and yellow bile, and phlegm) that early theorists believed controlled normal and abnormal functioning.

**Huntington's disease** Genetic disorder marked by involuntary limb movements and progressing to **dementia**.

**hypersensitive gag reflex** See **choking phobia**.

**hypersomnia** Abnormally excessive sleep. A person with this condition will fall asleep several times a day.

**hypertension** Major risk factor for **stroke** and heart and kidney disease that is intimately related to psychological factors. Also known as *high blood pressure.*

**hypnagogic hallucinations** Characteristic of **narcolepsy** involving frightening and vivid experiences during sleep that are visual, tactile, aural, and mobile.

**hypoactive sexual desire disorder** Apparent lack of interest in sexual activity or fantasy that would not be expected considering the person's age and life situation.

**hypochondriasis Somatoform disorder** involving severe **anxiety** over belief in having a disease process without any evident physical cause.

**hypofrontality** Relative deficiency in activity in the **frontal lobes** of the brains of people with **schizophrenia**; associated with the negative symptoms of the disorder.

**hypomanic episode** Less severe and less disruptive version of a **manic episode** that is one of the criteria for several **mood disorders**.

**hypothalamic–pituitary–adrenocortical (HPA) axis** Brain–endocrine system connection implicated in some **psychological disorders**.

**hypothalamus** Part of the brain that lies beneath the **thalamus** and is broadly involved in the regulation of behavior and **emotion**.

**hypothesis** Educated guess or statement to be tested by research.

**hypoventilation** Reduced or labored breathing—for example, during sleep.

**id** In **psychoanalysis**, the **unconscious** psychical entity present at birth representing basic drives.

**ideas of reference** Person's **delusion** that the actions, thoughts, laughter, and meaningless activities of others are directed toward or refer to that person.

**idiographic strategy** Close and detailed investigation of an individual emphasizing what makes that person unique (compare with **nomothetic strategy**).

**illness phobia** Extreme **fear** of the possibility of contracting a disease (as opposed to the belief in already having it), combined with irrational behaviors to avoid contracting it.

**imaginal exposure** Presentation or **systematic exposure** of **emotions** or fearful or traumatic experiences in the imagination.

**imipramine** One of the **tricyclic antidepressant** drugs affecting the serotonergic and noradrenergic **neurotransmitter** systems. It blocks **panic attacks** but not more generalized **anxiety** and causes side effects such as dry mouth, dizziness, and, occasionally, **sexual dysfunction**; effective in some **mood** and **anxiety** disorders, as well as other disorders.

**immune system** Body's means of identifying and eliminating any foreign materials (for example, bacteria, parasites, and even transplanted organs) that enter.

**implicit memory** Condition of memory in which a person cannot recall past events despite acting in response to them (contrast with **explicit memory**).

**impulse-control disorders** Disorders in which a person acts on an irresistible, but potentially harmful, impulse.

**inappropriate affect** Emotional displays that are improper for the situation.

**incest** Deviant sexual attraction **(pedophilia)** directed toward a family member; often the attraction of a father toward a daughter who is maturing physically.

**incidence** Number of new cases of a disorder appearing during a specific period (compare with **prevalence**).

**independent variable** Phenomenon manipulated by the experimenter in a study and expected to influence the **dependent variable**.

**inferiority complex** Feeling of being inferior to others while striving for superiority.

**informal observation** Attention paid to behavior but without defining or recording it in any systematic fashion.

**information transmission** Warnings about the feared object repeated so often that the person develops a **phobia** solely on the basis of hearing them.

**informed consent** Ethical requirement whereby research subjects agree to participate in a study only after they receive full disclosure about the nature of the study and their own role in it.

**inhibited orgasm** Inability to achieve orgasm despite adequate sexual desire and arousal; commonly seen in women but relatively rare in men.

**insanity** Legal rather than psychological or medical concept involving both a **psychological disorder** and an inability to know or appreciate the wrongfulness of criminal acts.

**insanity defense** Legal plea that a defendant should not be held responsible for a crime because that person was mentally ill at the time of the offense.

**insidious onset** Development of a disorder that occurs gradually over an extended period (contrast with **acute onset**).

**insight** In **psychoanalysis**, recognition of the causes of emotional distress.

**insulin shock therapy** Dangerous biological treatment involving the administration of large doses of insulin to induce seizures.

**intellectual disability (ID)** A diagnosis received when one achieves a significantly below-average score on a test of intelligence and by limitations in the ability to function in areas of daily life.

**intelligence quotient (IQ)** Score on an intelligence test estimating a person's deviation from average test performance.

**intermittent explosive disorder** Episodes during which a person acts on aggressive impulses that result in serious assaults or destruction of property.

**intermittent support intellectual disability** Intellectual disability level characterized by the need for only episodic special care—for example, during crises and difficult life changes.

**internal validity** Extent to which the results of a study can be attributed to the **independent variable** after confounding alternative explanations have been ruled out.

**interoceptive avoidance** Avoidance of situations or activities, such as exercise, that produce internal physical arousal similar to the beginnings of a **panic attack**.

**interpersonal psychotherapy (IPT)** Brief treatment approach that emphasizes resolution of interpersonal problems and stressors, such as role disputes, in marital conflict or forming relationships in marriage or a new job. It has demonstrated effectiveness for such problems as depression.

**interpersonal therapy** Brief, structured treatment that focuses on teaching a person skills to improve existing relationships or develop new ones.

**interrater reliability** Degree to which two or more observers make the same ratings or measurements.

**intersex individuals** People born with ambiguous genitalia and hormonal abnormalities. They are assigned a gender at birth and then often provided **hormones** and surgery to complete the correspondence. Also known as *hermaphrodites.*

**intrapsychic conflicts** In **psychoanalysis**, the struggles among the **id**, **ego**, and **superego**.

**introjection** In **object relations** theory, the process of incorporating memories and values of individuals who are important and close to the person.

**introspection** Early, nonscientific approach to the study of psychology involving systematic attempts to report thoughts and feelings that specific stimuli evoked.

**introversion** Tendency to be shy and withdrawn.

**inverse agonist** Chemical substance that produces effects opposite those of a particular **neurotransmitter**.

**isolated sleep paralysis** A period of time upon going to sleep or upon awakening in which a person cannot perform voluntary movements.

**ischemia** Narrowing of arteries caused by plaque buildup within the arteries.

**jealous type** Type of **delusional disorder** featuring **delusions** that the individual's sexual partner is unfaithful.

**jet lag type of circadian rhythm sleep disorder** Disorder in which sleepiness and alertness patterns conflict with local time and occur after recent or repeated travel across time zones.

**kleptomania** Recurrent failure to resist urges to steal things not needed for personal use or their monetary value.

***koro*** In Singapore, a condition of **mass hysteria** or group **delusion** in which people believe their genitals are retracting into their bodies.

**labeling** Applying a name to a phenomenon or a pattern of behavior. The label may acquire negative connotations or be applied erroneously to the person rather than that person's behaviors.

**la belle indifférence** Lack of distress shown by some individuals presenting conversion, somatization, or **amnestic disorders**.

**large fibers** Nerve fibers in the **dorsal horns of the spinal cord** that regulate the pattern and intensity of pain sensations. They close the gate, decreasing the transmission of painful stimuli.

**lateral ventricles** Naturally occurring cavities in the brain filled with cerebrospinal fluid. Some individuals with **schizophrenia** have enlarged ventricles, probably resulting from insufficient development or atrophy of surrounding tissue.

**law of effect** Edward L. Thorndike's principle that behaviors are strengthened or weakened by the environmental events that follow them.

**learned helplessness** Martin Seligman's theory that people become anxious and depressed when they make an attribution that they have no control over the **stress** in their lives (whether or not they do in reality).

**learning disorders** Reading, mathematics, or written expression performance substantially below levels expected relative to the person's age, IQ score, and education.

**Lesch-Nyhan syndrome** X-linked disorder characterized by **intellectual disability**, signs of cerebral palsy, and **self-injurious** behavior.

**leukocytes** White blood cells of varying types that play specialized roles in the **immune system** to fight viral and parasitic infections.

**level** Degree of behavior change with different interventions (for example, high or low).

**libido** In **psychoanalysis**, the energy within the **id** that drives people toward life and fulfillment.

**life-span developmental psychopathology** Study of **psychological disorders** over the entire age range.

**limbic system** Part of the **forebrain** involved in **emotion**, the ability to learn and to control impulses, and the regulation of sex, hunger, thirst, and aggression drives. This system figures prominently in much of **psychopathology**.

**limited support intellectual disability** Intellectual disability level characterized by the special care needed on a consistent although time-limited basis—for example, during employment training.

**lithium carbonate** Common salt used in substantial doses to treat bipolar disorder. Clients often discontinue its use because they enjoy the manic periods, and **relapse** rates are high. The mechanism for its effects is unknown.

**lobotomy** Neurosurgery procedure intended to eliminate undesirable behaviors by severing the connections between the **thalamus** or **hypothalamus** and the **frontal lobes** of the brain.

**localized or selective amnesia** Memory loss limited to specific times and events, particularly traumatic events.

**locus coeruleus** Area in the **hindbrain** that is part of a noradrenergic (norepinephrine-sensitive) circuit. It is involved in emergency and alarm reactions and may be related to **panic** states.

**longitudinal course** Time patterns among **mood disorders** (for example, prior dysthymia or cyclothymia **rapid cycling** and **seasonal pattern**) that may suggest their **course**, treatment, and **prognosis**.

**longitudinal design** Systematic study of changes in the same individual or group examined over time (contrast with **cross-sectional design**).

**loose associations** Deficits in logical continuity of speech, with abrupt movement between ideas. A characteristic of **schizophrenia** also called *derailment.*

**LSD (*d*-lysergic acid diethylamide)** Most common hallucinogenic drug; a synthetic version of the grain fungus ergot.

**Luria-Nebraska Neuropsychological Battery** Relatively precise instrument that helps identify and locate organic damage by testing various skills.

**lysergic acid amide** Naturally occurring **hallucinogen** found in the seeds of the morning glory plant.

**magnetic resonance imaging (MRI)** Procedure using radio signals generated in a strong magnetic field and passed through body tissue to produce detailed, even layered, images of its structure.

**maintenance of sameness** Necessity among people with **autism** that their familiar environments remain unchanged. They become upset when changes are introduced.

**maintenance treatment** Combination of continued **psychosocial treatment**, medication, or both designed to prevent **relapse** following therapy.

**major depressive disorder**, **single or recurrent episode Mood disorder** involving one *(single episode)* or more (separated by at least 2 months without depression—*recurrent*) **major depressive episodes**.

**major depressive episode** Most common and severe experience of depression, including feelings of worthlessness, disturbances in bodily activities such as sleep, loss of interest, and inability to experience pleasure, persisting at least 2 weeks.

**male erectile disorder** Recurring inability in some men to attain or maintain adequate penile erection until completion of sexual activity.

**male orgasmic disorder** Recurring delay in or absence of orgasm in some men following a normal sexual excitement phase, relative to age and current stimulation. Also known as **inhibited orgasm** (male).

**malingering** Deliberate faking of a physical or **psychological disorder** motivated by gain.

**mania** Period of abnormally excessive elation or euphoria, associated with some **mood disorders**.

**manic episode** Period of abnormally elevated or irritable **mood** that may include inflated self-esteem, decreased need for sleep, pressured speech, flight of ideas, agitation, or self-destructive behavior.

**marijuana *(Cannabis sativa)*** Dried part of the hemp plant; a **hallucinogen** that is the most widely used illegal substance.

**marital therapy** Interventions for the relationship problems of couples, whether married or not.

**mass hysteria** Phenomenon in which people in groups share the same **fear**, **delusion**, **abnormal behavior**, or even physical symptoms as a result of psychological processes and suggestion.

**mathematics disorder** Mathematics performance significantly below the standard for that age level.

**medroxyprogesterone** Medication that helps stimulate respiration and is used in treatment of **obstructive sleep apnea**.

**medulla** Part of the **hindbrain**, which regulates such automatic bodily functions as breathing and digestion.

**melatonin Hormone** produced by the pineal gland that is activated by darkness to control the body's biological clock and to induce sleep. It is implicated in **seasonal affective disorder** and may be used in treatments for **circadian rhythm sleep disorder**.

**memory B cells** Specialized lymphocytes created after **antigens** are neutralized to help the **immune system** fight off new invasions by those antigens more rapidly. These account for the effectiveness of inoculations.

**mental age** Score a person achieves on an intelligence test representing the highest age-equivalent items passed.

**mental disorder** See **psychological disorder**.

**mental hygiene movement** Mid-19th-century effort to improve care of the mentally disordered by informing the public of their mistreatment.

**mental illness** Term formerly used to mean **psychological disorder** but less preferred because it implies that the causes of the disorder can be found in a medical disease process.

**mental status exam** Relatively coarse preliminary test of a client's judgment, orientation to time and place, and emotional and mental state; typically conducted during an initial interview.

**mescaline** Naturally occurring **hallucinogen** found in the peyote cactus plant.

**methadone Opiate agonist** used as a treatment for heroin **addiction**. It initially provides the analgesic and sedative effects of heroin. After extended use, these effects diminish and **tolerance** develops. An effective treatment for some when combined with counseling.

**methylphenidate Stimulant** medicine (trade name Ritalin) used to treat **hypersomnia** (by keeping the person awake during the day); **narcolepsy**, including that with sudden onset (by suppressing **rapid eye movement sleep**); and **attention deficit/hyperactivity disorder**.

**microsleeps** Short, seconds-long periods of sleep that occur in people who have been deprived of sleep.

**midbrain** Section of the brain that coordinates movement with sensory input and contributes to the processes of arousal and tension.

**migraine headache** Debilitating, throbbing, or pulsing head pain with rapid onset, usually occurring on one side of the head.

**mild intellectual disability** Level of intellectual disability defined by IQ scores between 55 and 70.

**Minnesota Multiphasic Personality Inventory (MMPI)** Empirically derived standardized personality test that provides scales for assessing such abnormal functioning as depression and **paranoia**. One of the most widely used and heavily researched assessment instruments.

**mixed manic episode** Condition in which the individual experiences both elation and depression or **anxiety** at the same time. Also known as *dysphoric manic episode.*

**mixed sleep apnea** Combination of **obstructive** and **central sleep apnea**, such as brief interruptions in breathing during sleep caused by a blocked air passage and by cessation in respiratory activity.

**modeling** (also known as *observational learning*) Learning through observation and imitation of the behavior of other individuals and consequences of that behavior.

**moderate intellectual disability** Level of intellectual disability defined by IQ scores between 40 and 55.

**monoamine oxidase (MAO) inhibitors** Medications that treat depression and severe social **anxiety** by blocking an enzyme that breaks down the **neurotransmitters norepinephrine** and **serotonin**.

**mood** Enduring period of emotionality.

**mood congruent** Consistent with the person's emotional level. **Hallucinations** and **delusions** may be congruent or incongruent with a depressed person's **mood** (contrast with **mood incongruent**).

**mood disorders** Group of disorders involving severe and enduring disturbances in emotionality ranging from elation to severe depression.

**mood incongruent** Not consistent with the person's emotional level. **Psychotic symptoms** associated with **mood disorders** may not be congruent with the person's **mood** (contrast with **mood congruent**).

**mood-stabilizing drug** A medication used in the treatment of **mood disorders**, particularly bipolar disorder, that is effective in preventing and treating pathological shifts in mood.

**moral therapy** Psychosocial approach in the 19th century that involved treating patients as normally as possible in normal environments.

**moral weakness model of chemical dependence** View that substance abusers should be blamed because their behavior results from lack of self-control, character, or moral fiber.

**morphine Opiate** medication used as an analgesic (pain reliever) and narcotic that is sometimes a substance of abuse.

**multiaxial system** Categorization system, such as in *DSM-IV-TR,* employing several dimensions or **axes**, each used for differentiating among the categories.

**multidimensional integrative approach** Approach to the study of **psychopathology** that holds **psychological disorders** as always being the products of multiple interacting causal factors.

**multiple baseline Single-case experimental design** in which measures are taken on two or more behaviors or on a single behavior in two or more situations. A particular intervention is introduced for each at different times. If behavior change is coincident with each introduction, this is strong evidence the intervention caused the change.

**multiple infarctions** More than one area or incident of death to tissue (for example, in the brain or heart) because of blockage of blood flow.

**myocardial infarction** Death of heart tissue when its blood supply artery is blocked by plaque or a blood clot.

**myocardium** Heart muscle.

**naltrexone** Most widely used **opiate antagonist** drug. It produces immediate **withdrawal** and, thus, a great deal of discomfort. It may also contribute to the treatment of **alcohol** abuse but is not as successful for either substance as was originally hoped.

**narcissistic personality disorder** Cluster B (dramatic, emotional, or erratic) **personality disorder** involving a pervasive pattern of grandiosity in fantasy or behavior, need for admiration, and lack of **empathy**.

**narcolepsy** Sleep disorder involving sudden and irresistible **sleep attacks**.

**natural environment phobia** Fear of situations or events in nature, especially heights, storms, and water.

**negative affect** Emotional symptoms that are part of the definition of both **anxiety** and depression but are not specific to either of these. Also, **substance abuse** may be maintained because the substance causes an escape from unpleasant circumstances, responsibilities, or, especially, feelings.

**negative correlation** Association between two variables in which one increases as the other decreases.

**negative schema** Automatic, enduring, and stable negative cognitive bias or belief system about some aspect of life.

**negative symptoms** Less outgoing symptoms, such as **flat affect** and poverty of speech, displayed by some people with **schizophrenia**.

**negativistic personality disorder** Pervasive pattern of resisting routine requests and expectations and adopting a contrary attitude; considered for, but not included in, *DSM-IV.* Corresponds to former category known as **passive-aggressive personality disorder**.

**nervous breakdown** Lay term for a severe psychological upset that has no meaning in scientific or professional **psychopathology**.

**neurasthenia** Disorder common in the United States in the mid-1800s; the label is no longer used here (although it is still prevalent in China). Its symptoms include a lack of energy, a variety of aches and pains, and sometimes fever. This disorder is similar to present-day **chronic fatigue syndrome**.

**neuritic plaque** See **amyloid plaque**.

**neurofibrillary tangles** Brain damage in the form of large numbers of strandlike filaments found during autopsy in people with **Alzheimer's disease**.

**neurohormones Hormones** that affect the brain and are increasingly the focus of study in **psychopathology**.

**neuroimaging** Sophisticated computer-aided procedures that allow nonintrusive examination of nervous system structure and function.

**neuroleptics** Major antipsychotic medications, **dopamine antagonists**, that diminish **delusions**, **hallucinations**, and aggressive behavior in psychotic patients but may also cause serious side effects.

**neuromodulators Hormones** secreted into the blood to transmit brain messages throughout the body. Also known as *neuropeptides.*

**neuron** Individual nerve cell; responsible for transmitting information.

**neuropeptides** See **neuromodulators**.

**neuropsychological testing** Assessment of brain and nervous system functioning by testing an individual's performance on behavioral tasks.

**neuroscience** Study of the nervous system and its role in behavior, thoughts, and **emotions**.

**neurosis** Obsolete psychodynamic term for **psychological disorder** thought to result from **unconscious** conflicts and the **anxiety** they cause. Plural is *neuroses.*

**neurotransmitters** Chemicals that cross the **synaptic cleft** between nerve cells to transmit impulses from one **neuron** to the next. Their relative excess or deficiency is involved in several **psychological disorders**.

**nicotine** Toxic and addictive substance found in tobacco leaves.

**nicotine gum** Chewing gum that delivers **nicotine** to smokers without the carcinogens in cigarette smoke. This substitute may help people stop smoking, especially when combined with counseling.

**nicotine patch** Patch placed on the skin that delivers **nicotine** to smokers without the carcinogens in cigarette smoke. Somewhat more successful than nicotine gum because it requires less effort by the wearer and delivers the drug more consistently; should be coupled with counseling to stop smoking and avoid **relapse**.

**nicotine use disorders** Cognitive, biological, behavioral, and social problems associated with the use and abuse of **nicotine**.

**night eating syndrome** Consuming a third or more of daily food intake after the evening meal and getting out of bed at least once during the night to have a high-calorie snack. In the morning, however, individuals with night eating syndrome are not hungry and do not usually eat breakfast. These individuals do not **binge** during their night eating and seldom purge.

**nightmares** Frightening and anxiety-provoking dreams occurring during **rapid eye movement sleep**. The individual recalls the bad dreams and recovers alertness and orientation quickly.

**nocturnal enuresis** Urination while sleeping.

**nocturnal penile tumescence (NPT)** Erection of the penis during sleep, usually **rapid eye movement sleep**. If this normal reaction occurs in a man with erectile problems in the waking state, his problems may be assumed to have psychological origins.

**nomenclature** In a naming system or **nosology**, the actual labels or names that are applied. In **psychopathology**, these include **mood disorders** and eating disorders.

**nomothetic strategy** Identification and examination of large groups of people with the same disorder to note similarities and develop general laws (compare with **idiographic strategy**).

**nondemand pleasuring** Procedure to reestablish sexual arousal involving fondling and caressing while intercourse is forbidden. This method avoids the **anxiety** provoked by the need to perform sexually.

**nondisjunction** In **Down syndrome**, the failure of two of the 21st chromosomes to divide to create one cell with one copy that dies and one cell with three copies that continue to divide.

**nonrapid eye movement (NREM) sleep** Periods in the sleep cycle, divided into four substages, when the body may be active while the brain is relatively less active and dreaming does not occur.

**norepinephrine (also noradrenaline) Neurotransmitter** active in the **central** and **peripheral nervous systems**, controlling heart rate, blood pressure, and respiration, among other functions. Because of its role in the body's alarm reaction, it may also contribute generally and indirectly to **panic attacks** and other disorders.

**nosology Classification** and naming system for medical and psychological phenomena.

**nucleus accumbens** Complex of **neurons** that is part of the brain's "pleasure pathway" responsible for the experience of reward.

**obesity** Excess of body fat resulting in a body mass index (BMI, a ratio of weight to height) of 30 or more.

**object relations** Modern development in psychodynamic theory involving the study of how children incorporate the memories and values of people who are close and important to them.

**obsessions** Recurrent intrusive thoughts or impulses the client seeks to suppress or neutralize while recognizing they are not imposed by outside forces.

**obsessive-compulsive disorder (OCD) Anxiety** disorder involving unwanted, persistent, intrusive thoughts and impulses, as well as repetitive actions intended to suppress them.

**obsessive-compulsive personality disorder** Cluster C (anxious or fearful) **personality disorder** featuring a pervasive pattern of preoccupation with orderliness, perfectionism, and mental and interpersonal control at the expense of flexibility, openness, and efficiency.

**obstructive sleep apnea** Snoring and brief interruptions in breathing during sleep caused by blockage of the airway.

**occipital lobe** Section of each cerebral hemisphere that integrates and makes sense of visual inputs.

**Oedipus complex** In **psychoanalysis**, the intrapsychic struggle within a young boy between his lust for his mother and his **fear** of castration because of it. The resolution of this complex results in development of the **superego**.

**operant conditioning** Fundamental behavioral learning process in which responses are modified by their consequences (reinforcers, punishers, **extinction**, and so on).

**operational definition** Delineation of a concept on the basis of the operation used to measure it.

**opiates** Addictive **psychoactive substances** such as heroin, **opium**, and **morphine** that cause temporary euphoria and analgesia (pain reduction).

**opioid-releasing neurons** Nerve cells that release **endogenous opioids** and play a role in the brain's pleasure pathway controlling the experience of reward.

**opioid use disorders** Cognitive, biological, behavioral, and social problems associated with the use and abuse of **opiates** and their synthetic variants.

**opioids** Family of substances including **opiates** and **endorphins**, as well as synthetic variants such as **methadone**, that have a narcotic effect.

**opium** Naturally occurring compound from the poppy plant that is a strong narcotic, having pain-relieving and sleep- and euphoria-inducing effects. Its derivatives include **morphine** and heroin.

**opponent-process theory** Explanation of drug **tolerance** and dependence suggesting that when a person experiences positive feelings these will be followed shortly by negative feelings, and vice versa. Eventually, the motivation for drug taking shifts from a desire for the euphoric high to a need to relieve the increasingly unpleasant feelings that follow drug use. A vicious cycle develops: the drug that makes a person feel terrible is the one thing that can eliminate the pain.

**orgasmic reconditioning** Learning procedure to help clients strengthen appropriate patterns of sexual arousal by pairing appropriate stimuli with the pleasurable sensations of masturbation.

**orgasm phase** Stage of sexual activity involving ejaculation in men and vaginal wall contractions in women. Women are able to experience orgasm again immediately. Men are unable to form an erection for a time interval called a refractory period.

**oriented times three** Patients are aware of, or oriented to, their identity, location, and time (person, place, and time).

**outcome research** Studies examining the effectiveness and results, positive or negative, of treatment procedures.

**pain behaviors** Observable manifestations of the private experience of pain. These may include wincing or other facial expressions, verbal complaints of distress, and avoidance of activities that increase pain sensations.

**pain disorder Somatoform disorder** featuring true pain but for which psychological factors play an important role in onset, severity, or maintenance.

**panic** Sudden, overwhelming fright or terror.

**panic attack** Abrupt experience of intense **fear** or discomfort accompanied by a number of physical symptoms, such as dizziness or heart palpitations.

**panic control treatment (PCT) Cognitive-behavioral treatment** for **panic attacks**, involving gradual exposure to feared somatic sensations and modification of perceptions and attitudes about them.

**panic disorder with agoraphobia (PDA) Fear** and avoidance of situations the person believes might induce a dreaded **panic attack**.

**panic disorder without agoraphobia (PD) Panic attacks** experienced without development of **agoraphobia**.

**papaverine** Vasodilating medication used to treat male erectile disorder by dilating blood vessels, increasing blood flow to the penis to form an erection. The medication must be injected, and the procedure can be painful. It is so intrusive that it is often declined or discontinued by patients.

**paradoxical intention** Instructing clients to do the opposite of the desired behavior. Telling an impotent man not to have sex or an insomniac not to sleep reduces **anxiety** to perform.

**paranoia** People's irrational beliefs that they are especially important **(delusions of grandeur)** or that other people are seeking to do them harm.

**paranoid personality disorder** Cluster A (odd or eccentric) **personality disorder** involving pervasive distrust and suspiciousness of others such that their motives are interpreted as malevolent.

**paranoid type of schizophrenia** Type of **schizophrenia** in which symptoms primarily involve **delusions** and **hallucinations**; speech and motor and emotional behavior are relatively intact.

**paraphilias** Sexual disorders and deviations in which sexual arousal occurs almost exclusively in the context of inappropriate objects or individuals.

**parasomnias Abnormal behaviors** such as **nightmares** or **sleepwalking** that occur during sleep.

**parasympathetic nervous system** Part of the **autonomic nervous system** that regulates bodily systems (for example, digestion) while activity level is low and that balances **sympathetic nervous system** activity.

**parens patriae** Latin term (parent of his country) used to describe when the government takes on the role of guardian for a minor or person incapacitated.

**parietal lobe** Section of each cerebral hemisphere responsible for recognizing touch sensations.

**parkinsonian symptoms** See **extrapyramidal symptoms**.

**Parkinson's disease** Degenerative brain disorder principally affecting motor performance (for example, tremors and stooped posture) associated with reduction in **dopamine**. **Dementia** may be a result as well.

**passive-aggressive personality disorder** Former diagnostic category not included in *DSM-IV-TR* for lack of sufficient research. See a similar category: **negativistic personality disorder**.

**pathological gambling** Persistent and recurrent maladaptive gambling behavior.

**pathological or impacted grief reaction** Extreme reaction to the death of a loved one that involves psychotic features, **suicidal ideation**, or severe loss of weight or energy or that persists more than 2 months.

**patient uniformity myth** Tendency to consider all members of a category as more similar than they are, ignoring their individual differences.

**pedophilia Paraphilia** involving strong sexual attraction toward children.

**penile prosthesis** Surgical treatment for **male erectile disorder** involving the insertion of a prosthesis that may be a semirigid silicone rod or an inflatable tube.

**penile strain gauge** Psychophysiological monitoring device that measures male sexual arousal by changes in penis circumference.

**performance scales** In the Wechsler group of intelligence tests, subtests that assess psychomotor and nonverbal reasoning skills and the ability to learn new relationships.

**peripheral nervous system** Neural networks outside the brain and spinal cord, including the **somatic nervous system**, which controls muscle movement, and the **autonomic nervous system**, which regulates cardiovascular, endocrine, digestion, and regulation functions.

**permissive hypothesis** Theory that **neurotransmitter systems** contribute to **mood** irregularities when low **serotonin** levels permit them to range widely and become unregulated.

**persecutory type** A form of delusion that involves believing oneself (or someone close) is being malevolently treated in some way.

**personality disorders** Enduring maladaptive patterns for relating to the environment and self, exhibited in a range of contexts that cause significant functional impairment or subjective distress.

**personality inventories** Self-report questionnaires that assess personal traits by asking respondents to identify descriptions that apply to them.

**personality trait** Enduring tendency to behave in particular predisposed ways across situations.

**person-centered therapy** Therapy method in which the client, rather than the counselor, primarily directs the course of discussion, seeking self-discovery and self-responsibility.

**pervasive developmental disorders** Wide-ranging, significant, and long-lasting dysfunctions that appear before the age of 18.

**pervasive support intellectual disability** Intellectual disability level characterized by the constant, intensive care needed by the individual in all environments.

**phantom limb pain** Perception of pain in a limb that is absent because of amputation. This phenomenon suggests pain is not entirely a physical experience.

**phencyclidine (PCP)** Dangerous synthetic **hallucinogen**, also called angel dust, that may cause agitated or violent behavior, disorientation, convulsions, coma, and even death.

**phenotype** Observable characteristics or behaviors of an individual.

**phenylketonuria (PKU)** Recessive disorder involving the inability to break down a food chemical whose buildup causes intellectual disability, seizures, and behavior problems. PKU can be detected by infant screening and prevented by a specialized diet.

***phii pob*** Thailand's version of **dissociative trance** states.

**phobia** **Psychological disorder** characterized by marked and persistent **fear** of an object or situation.

**phobic avoidance** Extreme shunning of feared objects or situations displayed by people with **phobias**.

**phototherapy** Treatment of **seasonal affective disorder** with large doses of exposure to bright light.

**Pick's disease** Rare neurological disorder that results in **presenile dementia**.

***pivloktoq*** Running frenzy disorder among native peoples of the Arctic that seems equivalent to **dissociative fugue**.

**placebo** A nonactive treatment that is successful due to suggestion.

**placebo control group** In an outcome **experiment**, a **control group** that does not receive the experimental manipulation but is given a similar procedure with an identical expectation of change, allowing the researcher to assess any **placebo effect**.

**placebo effect** Behavior change resulting from the person's expectation of change rather than from the experimental manipulation itself.

**plasticity** Phenomenon by which damage to **neurons** sometimes can be compensated for by the action of other **neurons**.

**pleasure principle** Tendency to seek pleasure and minimize discomfort.

**polysomnographic (PSG) evaluation** Assessment of sleep disorders in which a client sleeping in the lab is monitored for heart, muscle, respiration, brain wave, and other functions.

**polysubstance use** Use of multiple mind- and behavior-altering substances, such as drugs.

**pons** Part of the hindbrain that controls such automatic bodily functions as breathing and digestion.

**positive correlation** Association between two variables in which one increases as the other increases.

**positive symptoms** More overt symptoms, such as **delusions** and **hallucinations**, displayed by some people with **schizophrenia**.

**positron emission tomography (PET) scan** Imaging procedure in which a radioactive tracer that binds to blood glucose is detected as the glucose is metabolized during brain activity. This allows nonintrusive localization and observation of brain activity.

**postpartum onset** Disorder that first appears in mothers during the time immediately following childbirth.

**posttraumatic stress disorder (PTSD)** Enduring, distressing emotional disorder that follows exposure to a severe helplessness- or fear-inducing threat. The victim reexperiences the trauma, avoids stimuli associated with it, and develops a numbing of responsiveness and an increased vigilance and arousal.

**prealcoholic stage** First of E. Morton Jellinek's four stages identified in the progression of alcoholism, involving occasional drinking with few serious consequences.

**predictive validity** Degree to which an assessment instrument accurately predicts a person's future behavior. See also **criterion validity**.

**premature ejaculation** Recurring ejaculation before the person wishes it, with minimal sexual stimulation.

**prepared learning** An ability has been adaptive for evolution, allowing certain associations can be learned more readily than others.

**presenile dementia** **Dementia** that appears before old age, between 40 and 60 years.

**presenting problem** Original complaint reported by the client to the therapist. The actual treated problem may sometimes be a modification derived from the presenting problem.

**prevalence** Number of people displaying a disorder in the total population at any given time (compare with **incidence**).

**primary gain** Freudian notion that **anxiety** reduction is the principal reinforcement obtained for the display of psychological symptoms.

**primary insomnia** Difficulty in initiating, maintaining, or gaining from sleep; not related to other medical or psychological problems.

**primary process** In psychodynamic theory, the **id**'s characteristic mode of thinking, which is emotional, irrational, and preoccupied with sex, aggression, and envy.

**proband** In genetics research, the individual displaying the trait or characteristic being studied.

**prodromal stage** Second of E. Morton Jellinek's four stages identified in the progression of alcoholism, featuring heavy drinking but with few outward signs of a problem.

**profound mental intellectual disability** Level of intellectual disability defined by IQ scores below 20 and extremely limited communication and self-help skills.

**prognosis** Predicted future development of a disorder over time.

**progressive muscle relaxation** Set of exercises to teach people to become aware of and actively counteract muscle tension to induce relaxation or drowsiness.

**projective tests** Psychoanalytically based measures that present ambiguous stimuli to clients on the assumption that their responses will reveal their **unconscious** conflicts. Such tests are inferential and lack high **reliability** and **validity**.

**prototypical approach** System for categorizing disorders using both essential, defining characteristics and a range of variation on other characteristics.

**psilocybin** Naturally occurring **hallucinogen** found in certain species of mushrooms.

**psychiatric nurse** Person with nursing training who specializes in care and treatment of psychiatric patients, usually in a hospital setting.

**psychiatric social worker** Person who has earned a master of social work (M.S.W.) degree or, occasionally, a doctor of social work (D.S.W.) degree and is trained to work with social agencies to help psychologically disordered clients and their families.

**psychiatrist** Person who has earned an M.D. degree and then has specialized in psychiatry during residency training. Such a person is trained to investigate primarily the biological nature and causes of psychiatric disorders and to diagnose and treat them.

**psychoactive substances** Substances, such as drugs, that alter **mood** or behavior.

**psychoanalysis** Psychoanalytic assessment and therapy, which emphasizes exploration of, and **insight** into, **unconscious** processes and conflicts, pioneered by Sigmund Freud.

**psychoanalyst** Therapist who practices **psychoanalysis** after earning either an M.D. or a Ph.D. degree and receiving additional specialized postdoctoral training.

**psychoanalytic model** Complex and comprehensive theory originally advanced by Sigmund Freud that seeks to account for the development and structure of personality, as well as the origin of **abnormal behavior**, based primarily on inferred inner entities and forces.

**psychodynamic psychotherapy** Contemporary version of **psychoanalysis** that still emphasizes **unconscious** processes and conflicts but is briefer and more focused on specific problems.

**psychological autopsy** Postmortem psychological profile of a suicide victim constructed from interviews with people who knew the person before death.

**psychological disorder** Psychological dysfunction associated with distress or impairment in functioning that is not a typical or culturally expected response.

**psychological model** Explanation of human behavior and its dysfunction that emphasizes the influence of the social environment and early experience.

**psychomotor intellectual disability** Deficits in motor activity and coordination development.

**psychoncology** Study of psychological factors involved in the **course** and treatment of **cancer**.

**psychoneuroimmunology (PNI)** Study of psychological influences on the neurological responding involved in the body's immune response.

**psychopathology** Scientific study of **psychological disorders**.

**psychopathy** Non-*DSM-IV-TR* category similar to **antisocial personality disorder** but with less emphasis on overt behavior. Indicators include superficial charm, lack of remorse, and other personality characteristics.

**psychopharmacogenetics** The study of how genetic makeup can affect individual reactions to drugs.

**psychophysiological assessment** Measurement of changes in the nervous system reflecting psychological or emotional events such as **anxiety**, **stress**, and sexual arousal.

**psychophysiological disorders** Outdated term, similar to **psychosomatic medicine**, for the study of psychological and social factors influencing physical disorders. The term is misleading because it falsely implies that other psychological problems, such as **mood disorders**, do not have significant biological components.

**psychosexual stages of development** In **psychoanalysis**, the sequence of phases a person passes through during development. Each stage is named for the location on the body where **id** gratification is maximal at that time.

**psychosis** Group of severe **psychological disorders**, including **schizophrenia**, featuring **delusions** and **hallucinations**.

**psychosocial treatment** Treatment practices that focus on social and cultural factors (such as family experience), as well as psychological influences. These approaches include cognitive, behavioral, and interpersonal methods.

**psychosomatic medicine** See **behavioral medicine**.

**psychosurgery** Biological treatment involving neurosurgery, such as **lobotomy**, for a **psychological disorder**. For example, a specific surgical lesion to the cingulate bundle may be an effective last-resort treatment for **obsessive-compulsive disorder**.

**psychotic behavior** Severe **psychological disorder** category characterized by **hallucinations** and loss of contact with reality.

**psychotic symptoms Delusions** and **hallucinations** that may appear during depressive or **manic episodes**.

**purging techniques** In the eating disorder **bulimia nervosa**, the self-induced vomiting or laxative abuse used to compensate for excessive food ingestion.

**pyromania** An **impulse-control disorder** that involves having an irresistible urge to set fires.

**quantitative genetics** Method of genetics research that examines patterns of genetic control over a range of **genes**, each of which may contribute only a small effect.

**randomization** Method for placing individuals into research groups that assures each an equal chance of being assigned to any group, thus eliminating any systematic differences across groups.

**rapid cycling** Temporal **course** of a bipolar disorder when transitions between **mania** and depression are quick, occurring four or more times in 1 year.

**rapid eye movement (REM) sleep** Periodic intervals of sleep during which the eyes move rapidly from side to side, and dreams occur, but the body is inactive.

**rauwolfia serpentina** More commonly known as *reserpine,* an early medication derived from the snakeroot plant that helps control the agitation and aggressiveness of some psychotic patients.

**Raynaud's disease Cardiovascular disease** involving blockage of blood circulation to the extremities, with resultant pain and cold sensations in the hands and feet.

**reactivity** Changes in one person's behavior as a result of observing the behavior in another.

**reading disorder** Reading performance significantly below the standard for that age level.

**reality principle** In psychodynamic theory, the logical reasoning style of the **ego** that ensures actions are practical and realistic.

**rebound insomnia** In a person with insomnia, the worsened sleep problems that can occur when medications are used to treat insomnia and then withdrawn.

**receptive language** Communicated material that is understood.

**receptors** Locations on nerve cell **dendrites** that receive chemical impulses for transmission through the **neuron**.

**recessive gene Gene** that must be paired with another recessive gene to determine a trait.

**reciprocal gene–environment model Hypothesis** that people with a genetic predisposition for a disorder may also have a genetic tendency to create environmental risk factors that promote the disorder.

**reexperiencing** Careful and systematic visualizing and reliving of traumatic life events to diminish their power and emotional effects as a means of treating **dissociative identity disorder** or **posttraumatic stress disorder**.

**regulated-breathing method** Intervention for **stuttering** in which the person is instructed to stop and take a deep breath whenever a stuttering episode begins.

**reinforcement** In **operant conditioning**, consequences for behavior that strengthen it or increase its frequency. Positive reinforcement involves the contingent delivery of a desired consequence. Negative reinforcement is the contingent escape from an aversive consequence. Unwanted behaviors may result from their reinforcement or the failure to reinforce desired behaviors.

**relapse** Reappearance of or return to problem behaviors after treatment or recovery.

**relapse prevention** Extending therapeutic progress by teaching the client how to cope with future troubling situations.

**relaxation response** Active components of meditation methods, including repetitive thoughts of a sound to reduce distracting thoughts and closing the mind to other intruding thoughts, that decrease the flow of **stress hormones** and **neurotransmitters** and cause a feeling of calm.

**reliability** Degree to which a measurement is consistent—for example, over time or among different raters.

**repeated measurement** When responses are measured on more than two occasions (not just before and after intervention) to assess trends.

**replication** Confirming the results of a study by repeating it, often by a separate, independent researcher.

**repressed memories** Concept involving recollections of traumatic events actively eliminated from memory. Controversy surrounds whether recall that seems to occur years later is real or accurate.

**repression** In psychoanalytic theory, a process that forces unwanted material from the conscious to the **unconscious**.

**research design** Plan of experimentation used to test a **hypothesis**.

**reserpine** See **rauwolfia serpentina**.

**residual type of schizophrenia** Diagnostic category for people who have experienced at least one episode of **schizophrenia** and who no longer display its major symptoms but still show some bizarre thoughts or social **withdrawal**.

**retarded ejaculation Male orgasmic disorder** in which ejaculation is delayed; thus, the patient is unable to reach orgasm with his partner, although he is able to ejaculate during masturbation.

**reticular activating system (RAS)** Section of the **midbrain** responsible for tension and arousal processes, including sleep and wakefulness.

**retrograde ejaculation** Condition in which ejaculatory fluids travel backward into the bladder, usually as a result of certain drugs or a medical condition. This is not considered a *DSM-IV-TR* **male orgasmic disorder**.

**retrospective information** Literally "the view back"; data collected by examining records or recollections of the past. It is limited by the accuracy, **validity**, and thoroughness of the sources.

**retrospective study** Research that uses **retrospective information** and shares its limitations.

**Rett's disorder** Progressive neurological developmental disorder featuring constant hand-wringing, **intellectual disability**, and impaired motor skills.

**reuptake** Action by which a **neurotransmitter** is quickly drawn back into the discharging **neuron** after being released into a **synaptic cleft**.

**reversal design** See **withdrawal design**.

**rheumatoid arthritis** Painful, degenerative disease in which the **immune system** essentially attacks itself, resulting in stiffness, swelling, and even destruction of the joints. **Cognitive-behavioral treatments** can help relieve pain and stiffness.

**Rhythm Test** Subtest of the **Halstead-Reitan Neuropsychological Battery** that asks respondents to compare rhythmic beats to assess sound recognition, attention, and concentration.

**Rorschach inkblot test Projective test** that uses irregular patterns of ink as its ambiguous stimuli.

**sadistic personality disorder** Pervasive pattern of deriving pleasure by inflicting pain on others; proposed as a category for *DSM-III-R* but not included in *DSM-IV-TR*.

**Saint Vitus's Dance** Instance of **mass hysteria** in which groups of people experienced a simultaneous **compulsion** to dance and shout in the streets. Also known as *tarantism.*

***sakit gila*** Disorder reported in Malaysia, similar to **schizophrenia** but different in important ways that may illuminate details of both disorders.

**scheduled awakening** For children who wake frequently at night, awakening them about an hour before their usual times and from a deeper sleep than usual to help them learn to fall asleep on their own.

**schedules of reinforcement** In **operant conditioning**, the pattern of consequences following a behavior based on the number of responses emitted or the time intervals between them.

**schizoaffective disorder** Psychotic disorder featuring symptoms of both **schizophrenia** and major **mood disorder**.

**schizoid personality disorder** Cluster A (odd or eccentric) **personality disorder** featuring a pervasive pattern of detachment from social relationships and a restricted range of expression of **emotions**.

**schizophrenia** Devastating psychotic disorder that may involve characteristic disturbances in thinking **(delusions)**, perception (**hallucinations**), speech, **emotions**, and behavior.

**schizophreniform disorder** Psychotic disorder involving the symptoms of **schizophrenia** but lasting less than 6 months.

**schizophrenogenic mother** According to an obsolete, unsupported theory, a cold, dominating, and rejecting parent who was thought to cause **schizophrenia** in her offspring.

**schizotypal personality disorder** Cluster A (odd or eccentric) **personality disorder** involving a pervasive pattern of interpersonal deficits featuring acute discomfort with, and reduced capacity for, close relationships, as well as cognitive or perceptual distortions and eccentricities of behavior.

**scientist-practitioners** Mental health professionals who are expected to apply scientific methods to their work. They must keep current in the latest research on **diagnosis** and treatment, they must evaluate their own methods for effectiveness, and they may generate their own research to discover new knowledge of disorders and their treatment.

**script theory** Theory of sexual functioning that suggests people's sexual behavior and attitudes are guided by scripts reflecting social and cultural expectations. Negative scripts may increase **vulnerability** to the development of **sexual dysfunction**.

**seasonal affective disorder (SAD) Mood disorder** involving a cycling of episodes corresponding to the seasons of the year, typically with depression occurring during the winter.

**seasonal pattern** Temporal **course** of bipolar or recurrent **major depressive disorders** in which episodes occur during particular seasons of the year.

**secondary gain** Additional reinforcers beyond **primary gain** that a person may obtain by the display of symptoms. These may include attention, sympathy, and avoidance of unwanted responsibilities.

**selective mutism** Developmental disorder characterized by the individual's consistent failure to speak in specific social situations despite speaking in other situations.

**self-actualizing** Process emphasized in humanistic psychology in which people strive to achieve their highest potential against difficult life experiences.

**self-defeating personality disorder** Pervasive pattern of being overly passive and accepting the pain and suffering imposed by others. A category proposed for *DSM-III-R* but not included in *DSM-IV-TR* for lack of research.

**self-efficacy** Perception of having the ability to cope with **stress** or challenges.

**self-injurious** Dangerous actions, including head-banging and hitting and biting oneself, seen in many children with **autism**.

**self-medication** Process by which some individuals may abuse substances in attempting to use them to relieve other problems such as **anxiety**, pain, or sleeplessness.

**self-monitoring** Action by which clients observe and record their own behaviors as either an assessment of a problem and its change or a treatment procedure that makes them more aware of their responses. Also called self-observation.

**self-psychology** See **ego psychology**.

**semistructured interviews** Interviews that employ preplanned, standardized questions to elicit information in a consistent way.

**sensate focus** Sex therapy in which couples concentrate on pleasurable sensations from caressing and fondling. Intercourse is forbidden to prevent focus on sexual performance and the **anxiety** it may provoke.

**sensorium** Person's general awareness of the surroundings, including time and place.

**sentence-completion method Projective test** in which the person is asked to finish a series of incomplete sentences.

**separation anxiety disorder** Excessive, enduring **fear** in some children that harm will come to them or their parents while they are apart.

**septum** Part of the **limbic system** that regulates **emotions** and the ability to learn and control impulses, as well as such drives as sex, hunger, thirst, and aggression.

**sequential design** Combination of the **cross-sectional** and **longitudinal designs** involving repeated study of different **cohorts** over time.

**serotonin Neurotransmitter** involved in processing of information and coordination of movement, as well as inhibition and restraint. It also assists in the regulation of eating, sexual, and aggressive behaviors, all of which may be involved in different **psychological disorders**. Its interaction with **dopamine** is implicated in **schizophrenia**.

**serotonin reuptake blockers** See **selective-serotonin reuptake inhibitors**.

**selective-serotonin reuptake inhibitors (SSRIs)** Class of medications for depression (including Prozac) that act on the serotonergic system by inhibiting the **reuptake** of the **neurotransmitter serotonin**.

**severe intellectual disability** Level of intellectual disability defined by IQ scores between 20 and 40 and with somewhat limited communication, self-help, social, and vocational skills.

**sex ratio** Percentage of men and women with a disorder.

**sex reassignment surgery** Surgical procedures to alter a person's physical anatomy to conform to that person's psychological gender identity.

**sexual aversion disorder** Extreme and persistent dislike of sexual contact or similar activities.

**sexual dysfunction** Sexual disorder in which the client finds it difficult to function adequately while having sex.

**sexual masochism Paraphilia** in which sexual arousal is associated with experiencing pain or humiliation.

**sexual pain disorders (dyspareunia)** Recurring genital pain in either males or females before, during, or after sexual intercourse.

**sexual sadism Paraphilia** in which sexual arousal is associated with inflicting pain or humiliation.

**shaping** In **operant conditioning**, the development of a new response by reinforcing successively more similar versions of that response. Both desirable and undesirable behaviors may be learned in this manner.

**shared psychotic disorder (folie à deux)** Psychotic disturbance in which individuals develop a **delusion** similar to that of a person with whom they share a close relationship.

**shift work type Circadian rhythm sleep disorder** characterized by insomnia during sleep time and sleepiness during wake time because of late-shift work or frequent work shift changes.

**silver nitrate** Chemical that can be used in gum or lozenges to make subsequent smoking aversive by producing a bad taste in the mouth. Research indicates this treatment approach is not particularly effective.

**single-case experimental design** Research tactic in which an **independent variable** is manipulated for a single individual, allowing cause-and-effect conclusions but with limited **generalizability** (contrast with **case study method**).

**single photon emission computed tomography (SPECT) Neuroimaging** procedure similar to a **positron emission tomography scan**, although less accurate, less complex, and less costly.

**sinoaortic baroreflex arc** Body mechanism to compensate for sudden blood pressure increases by decreasing pressure. This reaction causes some people to faint and may lead them to develop **phobias**.

**situationally bound**, **or cued**, **panic attack Panic attack** for which the triggering circumstances are known to the client.

**situationally predisposed panic attack** Circumstance that increases the likelihood a **panic attack** may be triggered.

**situational phobia Anxiety** involving enclosed places (for example, claustrophobia) or public transportation (for example, **fear** of flying).

**sleep apnea** Disorder involving brief periods when breathing ceases during sleep.

**sleep attacks** Unexpected episodes of falling asleep during the day.

**sleep efficiency (SE)** Percentage of time actually spent sleeping of the total time spent in bed.

**sleep hygiene** Psychological treatment for insomnia that teaches clients to recognize and eliminate environmental obstacles to sleep. These include the use of **nicotine**, caffeine, certain medications, and **alcohol**, as well as ill-timed exercise.

**sleep paralysis** Brief and frightening period at the beginning or end of sleep when the individual cannot move or speak; sometimes mistaken for nocturnal **panic attack**.

**sleep restriction** Treatment for insomnia that involves limiting time in bed to the actual amount spent sleeping so that the bed is associated with sleep and no other competing activities.

**sleep stress** Environmental events, such as ingesting excess caffeine, that can affect sleep negatively.

**sleep terrors** Episodes of apparent awakening from sleep, accompanied by signs of **panic**, followed by disorientation and amnesia for the incident. These occur during **nonrapid eye movement sleep** and so do not involve frightening dreams.

**sleepwalking Parasomnia** that involves leaving the bed during **nonrapid eye movement sleep**. See also **somnambulism**.

**slow wave sleep** See **delta waves**.

**small fibers** Nerve fibers in the **dorsal horns of the spinal cord** that regulate the pattern and intensity of pain sensations. They open the gate, increasing the transmission of painful stimuli.

**smooth-pursuit eye movement** Ability to follow moving targets visually. Deficits in this skill can be caused by a single **gene** whose location is known. This problem is associated with **schizophrenia** and, thus, may serve as a **genetic marker** for this disorder. Also called *eye-tracking.*

**social phobia** Extreme, enduring, irrational **fear** and avoidance of social or performance situations.

**sociopathic personality disturbances** Obsolete term corresponding to the current category **antisocial personality disorder**. It included **alcohol** and drug abuse because these were considered merely symptoms of other problems.

**somatic delusions** False and unfounded beliefs about the body—for example, that parts are rotting or turning to stone.

**somatic nervous system** Part of the **peripheral nervous system** that controls muscle movement.

**somatic treatments** Biological interventions that include medication, **electroconvulsive therapy**, and **psychosurgery**.

**somatization disorder Somatoform disorder** involving extreme and long-lasting focus on multiple physical symptoms for which no medical cause is evident.

**somatoform disorders** Pathological concern of individuals with the appearance or functioning of their bodies, usually in the absence of any identifiable medical condition.

**somnambulism** Repeated **sleepwalking** that occurs during **nonrapid eye movement sleep** and so is not the acting out of a dream. The person is difficult to waken and does not recall the experience.

**specific phobia** Unreasonable **fear** of a specific object or situation that markedly interferes with daily life functioning.

**specifiers** In **mood disorders**, patterns of characteristics that sometimes accompany **major depressive** or **manic episodes** and may help predict their **course** and **prognosis**. These include psychotic, melancholic, atypical, catatonic, chronic, and with **postpartum onset**.

**standardization** Process of establishing specific norms and requirements for a measurement technique to ensure it is used consistently across measurement occasions. This includes instructions for administering the measure, evaluating its findings, and comparing these to data for large numbers of people.

**Stanford-Binet test** Early standardized intelligence test designed to identify children who will experience academic difficulties by assessing their attention, perception, reasoning, and comprehension.

**statistical significance** Probability that obtaining the observed research findings merely by chance is small.

**statistics** Branch of mathematics concerned with gathering, analyzing, and interpreting data from research.

**stimulants Psychoactive substances** that elevate **mood**, activity, and alertness, including **amphetamines**, caffeine, **cocaine**, and **nicotine**.

**stimulus control** Deliberate arrangement of the environment so that it encourages desired behaviors and discourages problem behaviors. For example, insomnia may be combated by limiting time in, and associations with, the bed.

**Strength of Grip Test** Subtest of the **Halstead-Reitan Neuropsychological Battery** that compares the grip strength of the client's right and left hands.

**stress** Body's physiological response to a stressor, which is any event or change that requires adaptation.

**stress hormones** Group of **hormones**, including **corticosteroids**, involved in the body's physiological **stress** response.

**stress physiology** Study of the body's response to stressful events.

**stroke/cerebral vascular accident (CVA)** Temporary blockage of blood vessels supplying the brain, or a rupture of vessels in the brain, resulting in temporary or permanent loss of brain functioning.

**stuttering** Disturbance in the fluency and time patterning of speech (for example, sound and syllable repetitions or prolongations).

**subcortical dementia** Disease affecting the inner areas of the brain below the cortex. It differs from **dementia of the Alzheimer's type** in that it involves impaired recall but normal recognition, more severe depression and **anxiety**, slowed motions, and impaired coordination but no **aphasia**.

**sublimation** Psychodynamic **defense mechanism** in which the person redirects energy from conflict and **anxiety** into more constructive outlets, such as work.

**substance abuse** Pattern of **psychoactive substance** use leading to significant distress or impairment in social and occupational roles and in hazardous situations.

**substance dependence** Maladaptive pattern of substance use characterized by the need for increased amounts to achieve the desired effect, negative physical effects when the substance is withdrawn, unsuccessful efforts to control its use, and substantial effort expended to seek it or recover from its effects. Also known as *addiction.*

**substance intoxication** Physiological reactions, such as impaired judgment and motor ability, as well as **mood** changes, resulting from the ingestion of **psychoactive substances**.

**substance-related disorders** Range of problems associated with the use and abuse of drugs such as **alcohol**, **cocaine**, heroin, and other substances people use to alter the way they think, feel, and behave. These are extremely costly in human and financial terms.

**sufficient condition** Circumstance that, by itself, is enough to cause or allow a particular phenomenon to occur.

**suicidal attempts** Efforts made to kill oneself.

**suicidal ideation** Serious thoughts about committing suicide.

**suicidal plans** The formulation of a specific method of killing oneself.

**superego** In **psychoanalysis**, the psychical entity representing the internalized moral standards of parents and society.

**supernatural model** Explanation of human behavior and its dysfunction that posits important roles for spirits, demons, grace, sin, and so on.

**susceptibility** In genetics, **genes** that only slightly increase the risk of developing the disorder, but in contrast to the **deterministic** genes, these are more common in the general population.

**sympathetic nervous system** Part of the **autonomic nervous system** that prepares the body for activity or to respond to stressors—by increasing heart rate and blood flow to muscles, for instance.

**symptom substitution** Psychodynamic assertion that if overt problem behavior (the symptom) is treated without eliminating the underlying conflict thought to be causing it, that conflict will reemerge in the form of new, perhaps worse, symptoms.

**synaptic cleft** Space between nerve cells where chemical transmitters act to move impulses from one **neuron** to the next.

**systematic desensitization** Behavioral therapy technique to diminish excessive **fears**, involving gradual exposure to the feared stimulus paired with a positive coping experience, usually relaxation.

**systemic perspective** View that the many contributing causes of **abnormal behavior** form a system involving biology, behavior, cognition, **emotion**, culture, and society. Each component of the system affects all the others.

**systolic blood pressure** Blood pressure generated when the heart is at work pumping blood.

**T cells** Lymphocytes produced in bone marrow, developed in the thymus gland, and operating in the **cellular branch** of the **immune system**. Some attack **antigens** directly; others help regulate the system.

**tacrine hydrochloride** Medication for patients with **Alzheimer's disease** that prevents the breakdown of **acetylcholine**, keeping it available for use by the brain. Improvements are small, and the drug is expensive and causes serious side effects.

**Tactile Performance Test** Subtest of the **Halstead-Reitan Neuropsychological Battery** that asks the respondent to insert wooden shapes into a hidden form board, allowing the examiner to assess the subject's learning and memory skills.

***taijin kyofusho*** Japanese variant of **social phobia**. In many cases, individuals avoid social interaction because they believe they have terrible body or breath odor.

**tangentiality** Characteristic of the loose cognitive and verbal associations seen in **schizophrenia** in which the person fails to answer questions and quickly moves the conversation to unrelated topics.

**tarantism** See **Saint Vitus's Dance**.

**tardive dyskinesia Extrapyramidal symptom** and sometimes irreversible side effect of long-term **neuroleptic** medication, involving involuntary motor movements, especially in the face and tongue.

**task analysis** Method for evaluating a skill to be learned, breaking it down into its component parts.

**taxonomy** System of naming and **classification** (for example, of specimens) in science.

**telencephalon** See **forebrain**.

**telephone scatologia Paraphilia** in which the person gains sexual gratification by making obscene phone calls, usually while masturbating.

**temporal lobe** Section of each cerebral hemisphere associated primarily with sight and sound recognition and with long-term memory storage.

**temporal patterning Course** modifier for **mood disorders** describing their time sequences, including recurrence, recovery, and alternation.

**tension headaches** Bilateral head pain characterized by a dull ache, usually starting at the front or back of the head.

**tension reduction** Negative reinforcement motivation account for **substance abuse**, suggesting it is maintained because it allows people to escape **anxiety**.

**testability** Ability of a **hypothesis**, for example, to be subjected to scientific scrutiny and to be accepted or rejected, a necessary condition for the **hypothesis** to be useful.

**test–retest reliability** Degree to which results of two administrations of a test to the same person are similar.

**tetrahydrocannabinols (THC)** Most common active chemicals in **marijuana** responsible for its ability to alter **mood** and behavior.

**thalamus** Small region deep inside the brain broadly associated with regulation of behavior and **emotion**.

**thanatos** Freudian concept of a human drive toward death and destruction.

**Thematic Apperception Test (TAT) Projective test** in which the respondent is asked to tell stories about a series of ambiguous drawings.

**tic disorder** Disruption in early development involving involuntary motor movements or vocalizations.

**tics** Sudden, rapid, and recurrent involuntary motor movements or vocalizations.

**time-limited course** Condition in which a disorder improves on its own in a relatively brief period.

**time-management training** Instruction that teaches patients to deal with **stress** by establishing priorities among activities and demands and paying less attention to the less important ones.

**token economy** Social learning behavior modification system in which individuals earn items they can exchange for desired rewards by displaying appropriate behaviors.

**tolerance** Need for increased amounts of a substance to achieve the desired effect, and a diminished effect with continued use of the same amount.

**total sleep time** Actual combined time a person spends sleeping each day.

**Tourette's disorder** Developmental disorder featuring multiple dysfunctional motor and vocal **tics**.

**trainable intellectual disability** Obsolete term referring to level of intellectual disability comparable to the *DSM-IV-TR* "moderate" designation that suggests the individual can learn rudimentary vocational but not academic skills.

**transcendental meditation** Technique for focusing attention by softly repeating a single syllable (mantra); often accompanied by slow and regular breathing.

**transference** Psychoanalytic concept suggesting that clients may seek to relate to the therapist as they do to important authority figures, particularly their parents.

**transinstitutionalization** Movement of people with severe mental illness from large psychiatric hospitals to smaller group residences.

**transsexualism** Obsolete term for **gender identity disorder**.

**transvestic fetishism Paraphilia** in which individuals, usually males, are sexually aroused or receive gratification by wearing clothing of the opposite sex.

**treatment outcome research** Studies of the effectiveness of clinical interventions, including the comparison of competing treatments.

**trend** Direction of change of a behavior or behaviors (for example, increasing or decreasing).

**triazolam** Short-acting benzodiazepine medication (trade name Halcion) used to treat insomnia. Possible negative side effects include drowsiness, dependence, short-term memory loss, or rebound.

**trichotillomania** People's urge to pull out their own hair from anywhere on the body, including the scalp, eyebrows, and arm.

**tricyclic antidepressants** Most common treatment for depression, a group of medications including **imipramine** and amitriptyline that block the **reuptake** of **neurotransmitters**, principally **serotonin** and **norepinephrine**, at the synapse. The drugs are effective for some **anxiety** disorders and **mood disorders**. They are also used to treat **obstructive sleep apnea** because they help maintain respiratory muscle tone to assist breathing during **rapid eye movement sleep**. Positive effects are delayed, and negative side effects may include dizziness and even death, so close monitoring is required. **Relapse** rates range from 20% to 50% when the drug is stopped.

**tuberous sclerosis** Rare **dominant gene** disorder characterized by bumps on the skin and sometimes **intellectual disability** and seizures.

**twin studies** In genetics research, the comparison of twins with unrelated or less closely related individuals. If twins, particularly monozygotic twins who share identical **genotypes**, share common characteristics such as a disorder, even if they were reared in different environments, this is strong evidence of genetic involvement in those characteristics.

**type A behavior pattern** Cluster of behaviors including excessive competitiveness, time-pressured impatience, accelerated speech, and anger, originally thought to promote high risk for heart disease.

**type B behavior pattern** Cluster of behaviors including a relaxed attitude, indifference to time pressure, and less forceful ambition; originally thought to promote low risk for heart disease.

**unconditional positive regard** Acceptance by the counselor of the client's feelings and actions without judgment or condemnation.

**unconditioned response (UCR)** In **classical conditioning**, the natural or unlearned reaction to the **unconditioned stimulus**.

**unconditioned stimulus (UCS)** Environmental event that would elicit a response in almost anyone and requires no learning. In **classical conditioning**, it is paired with a neutral stimulus that, after training, may become a **conditioned stimulus**.

**unconscious** Part of the psychic makeup that is outside the awareness of the person.

**unconscious vision** See **blind sight**.

**underarousal hypothesis** Theory of the **etiology** of **antisocial personality disorder** suggesting psychopaths engage in dangerous or illicit behavior to stimulate the underaroused **cerebral cortex** in their brains.

**undifferentiated somatoform disorder** Somatization disorder with fewer than eight symptoms but still causing distress and impaired functioning.

**undifferentiated type of schizophrenia** Category for individuals who meet the criteria for **schizophrenia** but not for one of the defined subtypes.

**unexpected**, **or uncued**, **panic attack Panic attack** that has no identified triggering circumstance.

**unipolar mood disorder Mood disorder** characterized by depression or **mania** but not both. Most cases involve unipolar depression.

**unshared environments** Term indicating that even identical twins living in the same home may have different prenatal and family experiences.

**vacuum device therapy** Mechanical treatment for male erectile disorder that employs a vacuum cylinder to draw blood into the penis, where it is held by a ring placed at the base of the penis.

**vaginal photoplethysmograph** Light-sensitive psychophysiological monitoring device that measures female sexual arousal reflected by blood flow to the vagina.

**vaginismus** Recurring involuntary muscle spasms in the outer third of the vagina that interfere with sexual intercourse.

**validity** Degree to which a technique measures what it purports to measure.

**variability** Degree of change in a phenomenon over time.

**vascular** Pertaining to the vessels that transport blood and other fluids in the body.

**vascular dementia** Progressive brain disorder involving loss of cognitive functioning, caused by blockage of blood flow to the brain, that appears concurrently with other neurological signs and symptoms.

**vasovagal syncope** Fainting because of low blood pressure in the head and brain.

**ventral tegmental area Midbrain** region that includes part of the "pleasure pathway" responsible for the experience of reward.

**verbal scales** Sections of the Wechsler series of intelligence tests that assess vocabulary, memory, reasoning skills, and information facts.

***vinvusa*** Nigerian variant of **dissociative trance** states.

**visuospatial skills** Ability to see, recognize, orient within, and negotiate between objects in space.

**voyeurism Paraphilia** in which sexual arousal is derived from observing unsuspecting individuals undressing or naked.

**vulnerability Susceptibility** or tendency to develop a disorder.

**waxy flexibility** Characteristic of **catatonia** in which the person remains in bodily postures positioned by another person.

**Wechsler Adult Intelligence Scale—Revised (WAIS-R)** Intelligence test for adults, assessing a range of verbal and performance abilities.

**Wechsler Intelligence Scale for Children—3rd Edition (WISC-III)** Intelligence test for children assessing a range of verbal and performance abilities.

**Wechsler Preschool and Primary Scale of Intelligence—Revised (WPPSI-R)** Intelligence test for young children that measures a range of performance, verbal, and preverbal abilities.

**Wernicke–Korsakoff syndrome** Organic brain syndrome resulting from prolonged heavy **alcohol** use, involving confusion, unintelligible speech, and loss of motor coordination. It may be caused by a deficiency of thiamine, a vitamin metabolized poorly by heavy drinkers.

**withdrawal** Severely negative physiological reaction to removal of a **psychoactive substance**, which can be alleviated by the same or a similar substance.

**withdrawal delirium (delirium tremens/DTs)** Frightening hallucinations and body tremors that result when a heavy drinker withdraws from **alcohol**.

**withdrawal design** Removing a treatment to note whether it has been effective. In **single-case experimental designs**, a behavior is measured **(baseline)**, an **independent variable** is introduced (intervention), and then the intervention is withdrawn. Because the behavior continues to be measured throughout (repeated measurement), any effects of the intervention can be noted. Also called *reversal design.*

**X chromosome** One of the two sex chromosomes that determine gender; females have two and males have one, contributed by the mother. X chromosome abnormalities are implicated in some physical and cognitive problems.

**x-linked gene** A gene on the X chromosome.

**Y chromosome** One of the two sex chromosomes that determine gender; its presence, contributed by the father, determines the offspring will be male.

**Yerkes–Dodson curve** Inverted U-shaped graphical relationship between arousal and performance. Optimal performance occurs at intermediate levels of arousal. Psychopaths may engage in stimulus-seeking behavior to increase their low arousal to more useful levels.

# Subject Index

## A

- Abnormal behavior
  - biological tradition, 10–13
  - defined, 1
  - historical conceptions, 6–7
  - models of, 6
  - supernatural tradition, 7–10
- Acamprosate, 420
- Acedia, defined, 7
- Actigraph, 290
- Action tendency, 57
- *Actus rea,* 566
- Acute stress disorder, 155
- *Addington v. Texas,* 562, 564
- ADH. *See* Alcohol dehydrogenase (ADH)
- ADHD. *See* Attention deficit/hyperactivity disorder (ADHD)
- Adler, Alfred, 18–20
- Adolescents
  - bulimia, 270
  - conversion disorder in, 186
  - mood disorders and, 224–226
  - obese, 284–285
  - schizophrenia onset in, 481
  - somatization and, 179
  - suicides by, 251, 253
- Adolphine, 420
- Adoption studies, 112, 484
- Adrenal cortex, 230
- Adrenaline. *See* Epinephrine
- Advanced sleep phase type, 297
- Affect
  - defined, 57
  - inappropriate, 476
  - mental status exam and, 72
- Affective flattening, 475–476
- Age
  - ADHD onset, 506
  - BDD onset, 190
  - dementia onset, 539–540
  - depression onset, 218, 226
  - eating disorder onset, 270, 272
  - hypochondriasis onset, 175
  - intellectual disability onset, 522
  - IQ scores and, 81
  - maternal, Down syndrome and, 525
  - mature, 18
  - mood disorder onset, 224–226
  - schizophrenia onset, 481
  - somatization onset, 179
  - specific phobia onset, 146
- Agency for Health Care Policy and Research, 573
- Agency for Healthcare Research and Quality, 573
- Agnosia, 539
- Agonist substitution, 419–420
- Agoraphobia
  - development of, 134–135, 138
  - evolution of, 139–140
  - situational avoidance and, 135
- AIDS-related complex (ARC), 319
- Akinesia, 492
- Alarm reaction, 159
- Alcohol
  - blood concentrations, 397
  - body absorption of, 397
  - metabolism of, 399
  - production of, 397
  - response to, 413
- Alcohol abuse
  - aggregation and, 401
  - bulimia nervosa-associated, 267
  - clinical description, 397
  - effects of, 397–399
  - origins of, 396
  - progression of, 400–401
  - sexual dysfunction and, 366–367
  - statistics, 399–400
  - suicide and, 253
  - treatments for, 421–422
- Alcohol dehydrogenase (ADH), 399
- Alcoholics Anonymous, 421
- ALDH2 gene, 417
- Alogia, 474–475
- Alpha wave, 85
- Alpha-adrenergic receptors, 47
- Alprazolam, 140
- Alters, 197
- Altruistic suicides, 252
- Alzheimer's disease
  - biological factors, 546
  - clinical description of, 540–542
  - degeneration types in, 546
  - *DSM-IV-TR* criteria, 542
  - primary insomnia and, 291–292
  - statistics, 540–542
  - studies of, 541
  - testing for, 541
  - treatments for, 549
  - vaccine for, 552
- American Association on Intellectual and Development Disabilities, 522–523
- American Law Institute (ALI) rule, 565
- Amitriptyline, 241
- Amnestic disorders
  - characterization of, 553
  - dementia and, 535
  - testing for, 552
  - types of, 194–195
- Amniocentesis, 525
- Amphetamines
  - characterization of, 402
  - CNS effects, 403
  - dopamine and, 486
  - intoxication, 402–403
  - recreational use of, 411–412
- Amygdala, 42
- Amyloid beta peptides, 547
- Amyloid precursor protein, 547
- Anabolic-androgenic steroids, 411
- Analog models, 101
- Anhedonia, 475
- Animal phobias, 145
- Anna O., 15–16, 185, 198–199
- Anomic suicides, 252
- Anomie, 252
- Anorexia nervosa
  - AIDS-associated, 409
  - associated psychological disorders, 269
  - case study, 267
  - characterization of, 267–268
  - clinical description of, 268–269
  - course of, 270
  - cultural factors, 270
  - defined, 263
  - drug treatments for, 279
  - *DSM-IV-TR* criteria, 268
  - medical consequences of, 269
  - treatments for, 281–282
- Antabuse. *See* Disulfiram
- Antagonist treatments, 420
- Anti-psychotic drugs. *See also specific drugs*
  - categories of, 12
  - commonly used, 492
  - development of, 491–492
  - effectiveness of, 486, 492
  - noncompliance with, 492–494
  - side effects, 492
- Antibodies, 317
- Anticipated course, 5
- Antidepressants. *See also specific drugs*
  - mood disorders, 240–242
  - most commonly prescribed, 241
- Antigens, 318
- Antisocial personality disorder
  - arousal theories for, 449–450
  - case studies, 445–446, 448
  - clinical description of, 446–450
  - conduct disorder and, 448
  - criminality in, 447–448
  - defining criteria, 446–447
  - developmental influences, 450–451
  - *DSM-IV-TR* criteria, 446–447
  - gender differences in, 437
  - genetic influences, 448–449
  - neurobiological influences, 449–450
  - prevention of, 452
  - psychopathy in, 447–448
  - psychosocial factors, 450
  - somatization and, 180–181
  - substance abuse and, 395
  - treatments for, 451–451
- Anxiety
  - case study, 233
  - castration, 17
  - conversion disorder and, 186
  - defined, 123
  - effects of, 123–124
  - neurobiology of, 126–127
  - sexual arousal and, 367–368
  - sexual dysfunction and, 367
  - somatic symptoms of, 137
  - stress and, 314–316
- Anxiety disorders. *See also* Panic disorders
  - biological contributions, 125–127
  - brain structure and, 126
  - causes of, 125–128
  - characterization of, 57
  - children with, 5–6
  - comorbidity of, 128–129
  - depression and, 226
  - emerging conceptions of, 166–167
  - generalized, 129–134
  - genetic factors, 229–230
  - hypochondriasis and, 175–176
  - integrated model for, 127–128
  - OCD, 160–167
  - panic and, 58
  - physical disorders and, 128–129
  - primary insomnia and, 291–292
  - psychological factors, 127
  - PTSD, 154–160
  - social factors, 127
  - social phobias, 149–154
  - specific phobia, 143–149
  - suicide and, 129
  - summary, 167
  - terms, definitions of, 123–124
- Anxiety sensitivity index, 138–139
- Anxiolytic drugs, 401–402
- Aphasia, 544
- Apolipoprotein E4 (apo E4), 547
- Appearance, 72
- Arbitrary inference, 234
- ARC. *See* AIDS-related complex (ARC)
- Arousal
  - antisocial personality disorder, 449–450
  - anxiety and, 367–368
  - pedophilia and, 377–378
- Asclepiad Temples, 13
- ASPD. *See* Antisocial personality disorder (ASPD)
- Asperger's disorder, 518–519
- Assessment. *See* Clinical assessment
- Association studies, 113, 485
- Associative splitting, 470
- Asylum reform, 14
- *Ataques de nervios,* 137
- Atomoxetine, 508
- Attention deficit/hyperactivity disorder (ADHD)
  - adults with, 509
  - case study, 504
  - causes of, 507–508
  - clinical description, 505
  - defined, 504
  - diagnosis of, 506
  - *DSM-IV-TR* criteria, 505–506
  - innovative approaches to, 509
  - learning disorders and, 513
  - mood disorders and, 225
  - statistics, 505–506
  - treatments for, 508–510
- Attribution, 54
- Atypical behavior, 2
- Atypical features specifier, 215
- Auditory hallucinations, 214, 474
- Autistic disorder
  - biological factors, 517–518
  - case study, 514
  - characteristics of, 516
  - clinical description, 514–515

  communication impairment in, 515
  defined, 514
  *DSM-IV-TR* criteria, 516
  history of, 516–517
  neurobiological factors, 518
  psychosocial factors, 516–517
  social interaction impairment in, 515
  statistics, 516
Autonomic nervous system, 42–43
Aversive treatment, 420
Avoidant personality disorder
  case study, 459–460
  causes of, 460
  clinical description, 460
  *DSM-IV-TR* criteria, 460
  treatments for, 460
Avolition, 474
Axons, 38

## B

B cells, 317
Baby blues, 215
Barbiturates. *See also specific drugs*
  clinical description of, 401
  defined, 401
  statistics, 401–402
Bariatric surgery, 287–288
Basal ganglia, 42
Baseline, 109
*The Behavior of Organisms* (Skinner), 22
Behavior. *See also* Health-related behavior
  abstinence, 395
  across cultures, 115–116
  assessment of, 74–75
  disorganized, 476
  drug-seeking, 394
  genes, developments, 33–34
  heterosexual, 348
  homosexual, 348
  mental status exam and, 72
  modification of, 337–340
  nongenomic inheritance of, 37–38
  personality disorder and, 434
  rating scales, 77
  researching over time, 113–115
  types, 326
Behavior therapy, 21
Behavioral inhibition system (BIS), 126, 450
Behavioral medicine, 312
Behavioral model
  behaviorism and, 21
  classical conditioning, 20–21
  contributions of, 23
  defined, 20
  operant conditioning, 22
  therapy origins, 21–22
Behaviorism, 14, 21
Bender Visual–Motor Gestalt Test, 82
Benzodiazepines
  clinical description of, 401
  defined, 401
  GAD, 132–133
  panic disorders, 140
  statistics, 401–402
Beta-adrenergic receptors, 47
Beta-amyloid, 547
Beta-blockers, 47, 153
*Beyond Freedom and Dignity* (Skinner), 22
Bianchi, Kenneth, 197
Binge-eating disorder (BED)
  characterization, 269–270
  cultural factors, 271
  defined, 263
  drug treatment for, 279
  treatments for, 281
Binge-eating–purging anorexia, 268
Bini, Lucio, 12
Biofeedback, 85, 333–334
Biological model
  American, 11–12
  anxiety disorders, 125–127
  autism, 517
  Chinese, 11
  consequences of, 12–13
  defined, 6

# DSM-IV-TR CLASSIFICATION: AXES I AND II

## AXIS I

### Disorders Usually First Diagnosed in Infancy, Childhood, or Adolescence

**Learning Disorders (Academic Skills Disorders)**

Reading Disorder (Developmental Reading Disorder)/Mathematics Disorder (Developmental Arithmetic Disorder)/Disorder of Written Expression (Developmental Expressive Writing Disorder)

**Motor Skills Disorder**

Developmental Coordination Disorder

**Pervasive Developmental Disorders**

Autistic Disorder/Rett's Disorder/Childhood Disintegrative Disorder/Asperger's Disorder/PDD Not Otherwise Specified

**Disruptive Behavior and Attention-Deficit Disorders**

Attention-Deficit/Hyperactivity Disorder/Oppositional Defiant Disorder/Conduct Disorder

**Feeding and Eating Disorders of Infancy or Early Childhood**

Pica/Rumination Disorder/Feeding Disorder of Infancy or Early Childhood

**Tic Disorders**

Tourette's Disorder/Chronic Motor or Vocal Tic Disorder/Transient Tic Disorder

**Communication Disorders**

Expressive Language Disorder (Developmental Expressive Language Disorder)/Mixed Receptive/Expressive Language Disorder (Developmental Receptive Language Disorder)/Phonological Disorder (Developmental Articulation Disorder)/Stuttering

**Elimination Disorders**

Encopresis/Enuresis

**Other Disorders of Infancy, Childhood, or Adolescence**

Separation Anxiety Disorder/Selective Mutism (Elective Mutism)/Reactive Attachment Disorder of Infancy or Early Childhood/Stereotypic Movement Disorder (Stereotypy/Habit Disorder)

### Delirium, Dementia, Amnestic, and Other Cognitive Disorders

**Deliria**

Delirium Due to a General Medical Condition/Substance-Induced Delirium/Delirium Due to Multiple Etiologies

**Dementias**

Dementia of the Alzheimer's Type; With Early Onset: if onset at age 65 or below; With Late Onset: if onset after age 65/Vascular Dementia/Dementias Due to Other General Medical Conditions/Substance-Induced Persisting Dementia/Dementia Due to Multiple Etiologies

**Amnestic Disorders**

Amnestic Disorder Due to a General Medical Condition/Substance-Induced Persisting Amnestic Disorder (refer to specific Substance for code)

### Substance-Related Disorders

**Alcohol Use Disorders**

**Amphetamine (or Related Substance) Use Disorders**

**Caffeine Use Disorders**

**Cannabis Use Disorders**

**Cocaine Use Disorders**

**Hallucinogen Use Disorders**

**Inhalant Use Disorders**

**Nicotine Use Disorders**

**Opioid Use Disorders**

**Phencyclidine (or Related Substance) Use Disorders**

**Sedative, Hypnotic, or Anxiolytic Substance Use Disorders**

**Polysubstance Use Disorder**

### Schizophrenia and Other Psychotic Disorders

**Schizophrenia**

Paranoid Type/Disorganized Type/Catatonic Type/Undifferentiated Type/Residual Type

**Schizophreniform Disorder**

**Schizoaffective Disorder**

**Delusional Disorder**

**Brief Psychotic Disorder**

**Shared Psychotic Disorder (Folie à Deux)**

**Psychotic Disorder Due to a General Medical Condition**

With Delusions/With Hallucinations/Substance-Induced Psychotic Disorder

**Psychotic Disorder Not Otherwise Specified**

### Mood Disorders

**Depressive Disorders**

Major Depressive Disorder/Dysthymic Disorder/Depressive Disorder Not Otherwise Specified

**Bipolar Disorders**

Bipolar I Disorder/Bipolar II Disorder (Recurrent Major Depressive Episodes with Hypomania)/Bipolar Not Otherwise Specified/Cyclothymic Disorder

**Mood Disorder Due to a General Medical Condition**

**Substance-Induced Mood Disorder**

**Mood Disorder Not Otherwise Specified**

### Anxiety Disorders

**Panic Disorder**

Without Agoraphobia/With Agoraphobia

**Agoraphobia without History of Panic Disorder**

**Specific Phobia (Simple Phobia)**

**Social Phobia (Social Anxiety Disorder)**

**Obsessive-Compulsive Disorder**

**Posttraumatic Stress Disorder**

**Acute Stress Disorder**

**Generalized Anxiety Disorder (Includes Overanxious Disorder of Childhood)**

**Anxiety Disorder Due to a General Medical Condition**

**Substance-Induced Anxiety Disorder**

**Anxiety Disorder Not Otherwise Specified**

*(Continued on next page)*

## Somatoform Disorders

**Somatization Disorder**
**Conversion Disorder**
**Hypochondriasis**
**Body Dysmorphic Disorder**
**Pain Disorder**
**Somatoform Disorder Not Otherwise Specified**
**Undifferentiated Somatoform Disorder**

## Factitious Disorders

**Factitious Disorder**
**Factitious Disorder Not Otherwise Specified**

## Dissociative Disorders

**Dissociative Amnesia**
**Dissociative Fugue**
**Dissociative Identity Disorder (Multiple Personality Disorder)**
**Depersonalization Disorder**
**Dissociative Disorder Not Otherwise Specified**

## Sexual and Gender Identity Disorders

**Sexual Dysfunctions**

Sexual Desire Disorders: Hypoactive Sexual Desire Disorder; Sexual Aversion Disorder/Sexual Arousal Disorders: Female Sexual Arousal Disorder; Male Erectile Disorder/Orgasm Disorders: Female Orgasmic Disorder (Inhibited Female Orgasm); Male Orgasmic Disorder (Inhibited Male Orgasm); Premature Ejaculation/Sexual Pain Disorders: Dyspareunia; Vaginismus/Sexual Dysfunctions Due to a General Medical Condition/Substance-Induced Sexual Dysfunction

**Paraphilias**

Exhibitionism/Fetishism/Frotteurism/Pedophilia/Sexual Masochism/Sexual Sadism/Voyeurism/Transvestic Fetishism

**Gender Identity Disorders**

Gender Identity Disorder: in Children/in Adolescents and Adults (Transsexualism)

## Eating Disorders

**Anorexia Nervosa**
**Bulimia Nervosa**
**Eating Disorder Not Otherwise Specified**

## Sleep Disorders

**Primary Sleep Disorders**

Dyssomnias: Primary Insomnia; Primary Hypersomnia; Narcolepsy; Breathing-Related Sleep Disorder; Circadian Rhythm Sleep Disorder (formerly Sleep-Wake Schedule Disorder)/Parasomnias; Nightmare Disorder (Dream Anxiety Disorder); Sleep Terror Disorder; Sleepwalking Disorder/Sleep Disorders Related to Another Mental Disorder

**Sleep Disorder Due to a General Medical Condition**
**Substance-Induced Sleep Disorder**
**Dyssomnia Not Otherwise Specified**
**Parasomnia Not Otherwise Specified**

## Impulse Control Disorders Not Elsewhere Classified

**Intermittent Explosive Disorder**
**Kleptomania**
**Pyromania**
**Pathological Gambling**
**Trichotillomania**
**Impulse-Control Disorder Not Otherwise Specified**

## Adjustment Disorder

**Adjustment Disorder**
**With Anxiety**
**With Depressed Mood**
**With Disturbance of Conduct**
**With Mixed Disturbance of Emotions and Conduct**
**With Mixed Anxiety and Depressed Mood**
**Unspecified**

## Other Conditions That May Be a Focus of Clinical Attention

**Pyschological Factors Affecting Medical Condition**
**Medication-Induced Movement Disorders**
**Relational Problems**

Relational Problem Related to a Mental Disorder or General Medical Condition/Parent–Child Relational Problem/Partner Relational Problem/Sibling Relational Problem

**Problems Related to Abuse or Neglect**

Physical Abuse of Child/Sexual Abuse of Child/Neglect of Child/Physical Abuse of Adult/Sexual Abuse of Adult

**Additional Conditions That May Be a Focus of Clinical Attention**

Bereavement/Borderline Intellectual Functioning/Academic Problem/Occupational Problem/Childhood or Adolescent Antisocial Behavior/Adult Antisocial Behavior/Malingering Phase of Life

Problem/Noncompliance with Treatment for a Mental Disorder/ Identity Problem/Religious or Spiritual Problem/Acculturation Problem/ Age-Associated Memory Decline

# AXIS II

## Personality Disorders

**Paranoid Personality Disorder**
**Schizoid Personality Disorder**
**Schizotypal Personality Disorder**
**Antisocial Personality Disorder**
**Borderline Personality Disorder**
**Histrionic Personality Disorder**
**Narcissistic Personality Disorder**
**Avoidant Personality Disorder**
**Dependent Personality Disorder**
**Obsessive-Compulsive Personality Disorder**

**Mental Retardation**

Mild Mental Retardation/Moderate Mental Retardation/Severe Mental Retardation/Profound Mental Retardation

# DISORDERS NEEDING FURTHER STUDY

The DSM-IV Task Force judged that these disorders do not currently have sufficient supporting data for inclusion in DSM-IV and therefore require further study. In fact, only a few of these proposed disorders will ultimately meet criteria, while others will be excluded from further consideration. Many of the more interesting disorders are discussed in one or more appropriate chapters.

## Postconcussional Disorder

The key features of this disorder are specific cognitive impairments as well as excessive fatigue, disordered sleep, and headaches following a head trauma that resulted in a concussion. (See related material in Chapter 13.)

## Mild Neurocognitive Disorder

The key feature of this disorder is an impairment in neurocognitive functioning that is the result of a general medical condition. (See Chapter 13.)

## Caffeine Withdrawal

The key feature of this disorder is the experience of headaches, fatigue, anxiety, nausea, or vomiting after the abrupt cessation of caffeine consumption following prolonged daily use of the substance. (See related material in Chapter 10.)

## Alternative Dimensional Descriptors for Schizophrenia

A three-factor dimensional model (psychotic, disorganized, and negative) has been suggested to describe current and lifetime symptomatology. The psychotic factor includes delusions and hallucinations. The disorganized factor includes disorganized speech, disorganized behavior, and inappropriate affect. (See Chapter 12.)

## Postpsychotic Depressive Disorder of Schizophrenia

The key feature of this disorder is a major depressive episode that occurs only during the residual phase of schizophrenia. (See related material in Chapter 6.)

## Simple Deteriorative Disorder (Simple Schizophrenia)

The key feature of this disorder is the development of prominent negative symptoms (e.g., alogia, avolition) in the absence of positive symptoms (e.g., hallucinations, delusions) over the course of 1 year. (See related material in Chapter 12.)

## Premenstrual Dysphoric Disorder

The key features of this disorder are marked anxiety or depressed mood, affective lability, and decreased interest in activities. These symptoms regularly occur during the week preceding menses and are never present during the week following it. (See Chapter 3.)

## Minor Depressive Disorder

The key feature of this disorder is one or more periods of depressive symptoms that have the same duration as a major depressive episode but fewer and less severe symptoms. (See related material in Chapter 6.)

## Recurrent Brief Depressive Disorder

The key feature of this disorder is one or more periods of depressive symptoms. The symptoms are equal in number and degree of impairment to those seen in a major depressive episode, but they last for less than 2 weeks. (See related material in Chapter 6.)

## Mixed Anxiety–Depressive Disorder

The key feature of this disorder is the presence of persistent or recurrent dysphoric mood as well as a number of symptoms of negative affect for at least 1 month. (See Chapter 6).

## Factitious Disorder by Proxy

The essential feature is the deliberate production or feigning of physical or psychological signs or symptoms in another person who is under the individual's care. Typically the victim is a young child and the perpetrator is the child's mother. (See Chapter 5.)

## Dissociative Trance Disorder

The key feature of this disorder is an involuntary state of trance that is not considered normal within the person's culture or religion and causes significant distress or impairment. (See Chapter 5.)

## Binge-Eating Disorder

The key feature of this disorder is the repeated occurrence of binge eating. The person has impaired control over the bingeing and is distressed by it. Compensatory behaviors, such as those typical of bulimia nervosa, are absent. (See related material in Chapter 8.)

## Depressive Personality Disorder

The key feature of this disorder is a pervasive pattern of depressive thoughts and behaviors that develops by early adulthood and occurs in a variety of contexts. The symptoms are not better accounted for by dysthymia and do not occur only during major depressive episodes. (See related material in Chapters 6 and 11.)

## Passive-Aggressive Personality Disorder (Negativistic Personality Disorder)

The key feature of this disorder is a pattern of negativistic attitudes and the use of passive means to resist occupational and social demands. This pattern develops by early adulthood and occurs in a variety of contexts. (See Chapter 11.)

## Medication-Induced Movement Disorders

This category of disorders was designed to assist in the management of medication and the assignment of psychological diagnoses. The key features of these disorders are abnormal physical movements or characteristics such as tremors, muscle rigidity or spasms, pacing, fidgety behavior, or abnormal posture that are judged to be side effects of specific medications. The following diagnoses have been proposed for this category: Neuroleptic-Induced Parkinsonism, Neuroleptic Malignant Syndrome, Neuroleptic-Induced Acute Dystonia, Neuroleptic-Induced Acute Akathisia, Neuroleptic-Induced Tardive Dyskinesia, Medication-Induced Postural Tremor, Medication-Induced Movement Disorder Not Otherwise Specified. (See related material in Chapter 13.)
